Like X-ray tomography, SPECT imaging requires the rotation of a photon detector array around the body to acquire data from multiple angles. Using this technique, the position and concentration of the radionuclide distribution can be determined. Because the emission sources (in this case injected radiopharmaceuticals) are inside the body, this is more difficult than for X-ray tomography, where the source position and strength are known because the X-ray source is outside the body. It is necessary to compensate for the attenuation experienced by emission photons from injected tracers in the body and contemporary SPECT machines use mathematical reconstruction algorithms to generate the image taking this into account.

SPECT imaging has lower attainable resolution and sensitivity than positron emission tomography (PET). The radionuclides that are used for SPECT imaging emit a single gamma ray photon (usually about 140 keV), whereas in PET the positron emission results in two high-energy gamma ray 511 keV photons.

Methods and Instrumentation

The technique requires the detection of the gamma rays emitted by the distribution of the radiopharmaceutical in the body. These gamma rays have to be collimated for detection by a gamma ray camera. The collimators contain thousands of parallel channels made of lead with square, circular or hexagonal cross sections through which the gamma rays pass. These typically weigh about 25 kg and are about 5 cm thick with a length and breadth of about 40 by 20 cm. Models for special high-energy studies can be much more substantial and can weigh up to 100 kg. Such a collimator is termed a parallel-hole collimator and has a resolution which increases with distance from the gamma ray source. The resolution can be altered by using channels of different sizes. By going to smaller channels there is a trade-off in sensitivity. This has to be borne in mind during patient studies as it has an effect on scan times. Other types of collimator have been developed and these include converging hole collimators. Collimators are positioned above a very delicate single crystal of sodium iodide which is the heart of a gamma camera. This type of collimator/camera arrangement is called an Anger camera after its inventor.

The gamma rays emitted by the radiopharmaceutical in the body can be scattered by electrons within molecules in the body. This is known as Compton scattering and some such scattered photons are thus lost to the Anger camera because of the deflections caused. Second, the gamma rays can cause a photoelectron effect within an atom in the body (promotion of an electron to a higher orbital or even release of the electron) and again this gamma photon will be lost to the detection process.

Usually, Compton scattering is the most probable cause of attenuation in a SPECT image. Conversely, it is possible for a Compton scattered photon to be deflected

into the Anger camera's field of view and in this case there is no information available on where the gamma photon originated and hence no spatial information on the location of the radiopharmaceutical. This process leads to loss of image contrast. A typical Anger camera equipped with a low-energy collimator detects only about 1 in 10^4 gamma photons emitted by the radiopharmaceutical and a modern Anger camera has an intrinsic resolution of between 3 and 9 mm.

A gamma ray which passes through the collimator assembly will hit the sodium iodide crystal and generate a light photon which interacts with a grid of photomultiplier tubes behind and which collects the light for further processing. SPECT images are produced from these light signals. Sensitivity has been improved by the introduction of multi-camera SPECT systems. A triple-camera SPECT system equipped with high-resolution parallel-hole collimators can produce a resolution of 4–7 mm. Finally, other types of collimator such as the so-called pin-hole type have been designed for imaging small organs such as the thyroid gland or limb extremities and for studies on laboratory animals.

The signals for the detected photons are reconstructed into an image using algorithms originally based on those used for X-ray tomography but which allowed for photon attenuation and Compton scattering. A typical method would be the filtered back-projection approach.

A number of experimental parameters have to be optimized in order to obtain the best SPECT image. These include attenuation, scatter, linearity of detector response, spatial resolution of the collimator and camera, system sensitivity, minimization of mechanical movements, image slice thickness, reconstruction matrix size and filter methods, sampling intervals and system dead-time. In a hospital, calibrating and monitoring these functions are usually performed by a Certified Nuclear Medicine Technician or a medical physicist.

Applications

SPECT is used routinely to help diagnose and stage the development of tumours and to pinpoint stroke, liver disease, lung disease and many other physiological and functional abnormalities. Although SPECT imaging resolution is not as high as that of PET, the availability of new SPECT radiopharmaceuticals, particularly for the brain and head, and the practical and economic aspects of SPECT instrumentation make this mode of emission tomography particularly attractive for clinical studies of the brain.

Introduction

Spectroelectrochemistry encompasses a group of techniques that allow simultaneous acquisition of spectroscopic and electrochemical information *in situ* in an electrochemical cell. Electrochemical reactions can be initiated by applying potentials to the working electrode, and the processes that occur are then monitored by both electrochemical and spectroscopic techniques. Electronic (UV-visible) transmission and reflectance spectroelectrochemistry has proved to be an effective approach for studying the redox chemistry of organic, inorganic and biological molecules, for investigating reaction kinetics and mechanisms, and for exploring electrode surface phenomena. In this article a selection of representative examples are presented, the emphasis being on the applications of transmission electronic

(UV-visible) spectroelectrochemistry to the study of redox reactions and homogeneous chemical reactions initiated electrochemically within the boundaries of the diffusion layer at the electrode–electrolyte interface.

Organic Systems

Many organic systems exhibit redox states with distinct electronic (UV-visible) absorption spectra and are therefore amenable to study with spectroelectrochemical techniques.

o-Tolidine

The technique of transmission spectroelectrochemistry, using an optically transparent electrode (OTE), was first demonstrated in 1964 using *o*-tolidine, a colourless compound that reversibly undergoes a 2-electron oxidation in acidic solution to form an intensely yellow coloured species (eqn [1]). This system soon became a standard for testing spectroelectrochemical cells and new techniques.

Figure 1 shows absorbance spectra, for a series of applied potentials, recorded in an electrochemical cell employing an optically transparent thin-layer electrode (OTTLE). Curve a was recorded after application of +0.800 V vs saturated calomel electrode (SCE), which under thin-layer electrode conditions causes complete electrolytic oxidation of *o*-tolidine to the yellow form ([O]/[R] > 1000, where O represents the oxidized form and R the reduced form). Curve g was recorded after application of +0.400 V, causing complete electrolytic reduction ([O]/[R] < 0.001), with the intermediate spectra corresponding to intermediate values of E_{applied} . The absorbance at 438 nm reflects the amount of *o*-tolidine in the oxidized form, which can be calculated from the Beer–Lambert law.

Determination of E^0 , the reversible electrode potential, and n , the number of electrons in the *o*-tolidine redox reaction, can be determined from the sequence of spectropotentiostatic measurements (Figure 1). For a

Figure 1 Thin-layer spectra of 0.97 mM *o*-tolidine, 0.5 M ethanoic acid, 1.0 M HClO₄ for different values of E_{applied} . Cell thickness 0.017 cm. Potential vs SCE: (a) 0.800 V, (b) 0.660 V, (c) 0.640 V, (d) 0.620 V, (e) 0.580 V, (f) 0.600 V, (g) 0.400 V. reversible system,

the [O]/[R] ratio at the electrode surface is controlled by the applied potential according to the Nernst equation:

$$E_{\text{applied}} = E^0 + \frac{RT}{nF} \ln \left(\frac{[\text{O}]}{[\text{R}]} \right)_{\text{surface}} \quad [3]$$

In an OTTLE cell, on application of a new potential, the concentrations of O and R in solution are quickly adjusted to the same values as those existing at the electrode surface. Thus, at equilibrium:

$$\left(\frac{[\text{O}]}{[\text{R}]} \right)_{\text{surface}} = \left(\frac{[\text{O}]}{[\text{R}]} \right)_{\text{solution}} \quad [4]$$

The Nernst equation in a thin-layer cell can then be written as:

$$E_{\text{applied}} = E^0 + \frac{RT}{nF} \ln \left(\frac{[\text{O}]}{[\text{R}]} \right) \quad [5]$$

For the *o*-tolidine spectra, 438 nm is used as the monitoring wavelength and the ratio [O]/[R] is determined

Figure 2 Plot of E_{applied} vs $\log([\text{O}]/[\text{R}])$ from the spectra in **Figure 1**. Reprinted with permission from the DeAngelis TP and Heineman WR (1976) *Journal of Chemical Education* 53: 594–597. © 1976 Division of Chemical Education, American Chemical Society.

from the Beer–Lambert law:

$$\frac{[\text{O}]}{[\text{R}]} = \frac{(A_2 - A_1)/\Delta\epsilon b}{(A_3 - A_2)/\Delta\epsilon b} = \frac{A_2 - A_1}{A_3 - A_2} \quad [6]$$

where A_1 is the absorbance of the reduced form, A_3 is the absorbance of the oxidized form, A_2 is the absorbance obtained at an intermediate applied potential, $\Delta\epsilon$ is the difference in molar absorptivity between O and R at 438 nm and b is the light path length in the thin-layer cell. Thus the Nernst equation can be expressed as

$$E_{\text{applied}} = E^0 + \frac{RT}{nF} \ln \left(\frac{A_2 - A_1}{A_3 - A_2} \right) \quad [7]$$

Figure 2 gives E_{applied} vs $\log([\text{O}]/[\text{R}])$ for the data from **Figure 1**. The plot is linear as predicted from eqn [7], the slope being 0.031 V, which corresponds to an n value of 1.92, with an intercept of 0.612 V vs SCE.

Methyl Viologen

Mechanistic information is often available from spectroelectrochemical measurements. To illustrate the acquisition of semiquantitative information using a rapid

Pyrene Reduction

Reduction of the polycyclic aromatic pyrene serves as another excellent example of an EE mechanism where follow-up chemical reactions complicate the overall mechanism (**Figure 3**).

The one-electron reduction to the radical anion produces a ground doublet state with allowed transitions expected in the visible region of the spectrum. Spectra taken by RSS during chronoamperometric reduction at a potential 0.200 V more negative than E_p of the first wave $E_p = -2.06$ V vs SCE in acetonitrile-TEAP (tetra-ethylammonium perchlorate) showed only a major band with a wavelength maximum at 492 nm in the visible region (**Figures 3a** and **3c**). Reduction at E_p of the second wave produced spectra with wavelength maxima at 455 and 520–530 nm (**Figure 3a**, curve **b**). These maxima are similar to those for a spectrum obtained from the chemical reduction of pyrene and attributed to the dianion, except that the long-wavelength band at 602 nm reported earlier is absent. There is doubt, however, that this spectrum is the dianion because the second wave is irreversible; a new oxidation wave more positive in potential than the wave for the oxidation of the radical anion appears (**Figure 3c**); and no spectrum due to the free radical appears during chronoamperometric reduction at E_p of the second wave. In any EE mechanism where the waves are sufficiently separated that the equilibrium constant for the disproportionation reaction is large, the equilibrium between the three species (pyrene, radical anion and dianion) would favour the presence of the radical anion in the diffusion layer. The supposed absence of rapid electron exchange between pyrene and dianion to form the radical anion suggests an EEC mechanism in which the dianion undergoes a fast homogeneous chemical reaction to a species more stable than the radical. A likely candidate is the monoanion formed through protonation.

Inorganic Systems

There is a wide range of inorganic systems amenable to study by the spectroelectrochemical approach. In particular, transition metal complexes, with their rich redox state-dependent electronic spectra, have been intensively studied.

Hexacyanoferrate(III/II)

The hexacyanoferrate(III/II) (ferricyanide/ferrocyanide) system in aqueous solution is a well-known electrochemically reversible redox couple (eqn [10]).

Figure 3 Spectra and cyclic voltammograms for the reduction of pyrene. (a) Curve a, spectrum of monoanion radical; $\lambda_{\max}$ 492, 446, 385 nm; curve b, spectrum obtained from reduction at the second wave for pyrene (see (c)); $\lambda_{\max}$ 455 and 520–530 nm. (b) Cyclic voltammogram for the reduction of pyrene to the monoanion radical in acetonitrile–TEAP at a tin oxide OTE. (c) Cyclic voltammogram for the reduction of pyrene. After reduction at the second wave, a new oxidation wave more positive than for the oxidation of the radical appears. Reprinted by courtesy of Marcel-Dekker, Inc. from Kuwana T and Winograd N (1974) Spectroelectrochemistry at optically transparent electrodes. I. Electrodes under semi-infinite diffusion conditions. In: Bard AJ (ed.) *Electroanalytical Chemistry. A Series of Advances*, vol 7, pp. 1–78. New York: Marcel-Dekker.

Furthermore, as the hexacyanoferrate(III) ion is brilliant yellow in colour and the hexacyanoferrate(II) ion is only very pale yellow, this redox couple is particularly suited as a model system for electronic (UV-visible) absorbance spectroelectrochemical studies.

Figure 4 shows UV-visible absorption spectra recorded in a spectropotentiostatic experiment in an OTTLE cell on reduction of hexacyanoferrate(III) at a sequence of applied potentials. Curve a is at +0.50 V vs SCE reference electrode, where the redox system is in the oxidized state ($[\text{Fe}^{\text{III}}(\text{CN})_6]^{3-}/[\text{Fe}^{\text{III}}(\text{CN})_6]^{4-} > 1000$). Curve h is at +0.00 V vs SCE, where the redox system is in the reduced state ($[\text{Fe}^{\text{III}}(\text{CN})_6]^{4-}/[\text{Fe}^{\text{III}}(\text{CN})_6]^{3-} > 1000$), while the intermediate spectra correspond to intermediate values of applied potentials. The inset plot in **Figure 4** demonstrates the reversibility of this system in accordance with eqn [7].

$[\text{Tc}^{\text{III}}(\text{diars})_2\text{Cl}_2]^+$

The complex $[\text{Tc}^{\text{III}}(\text{diars})_2\text{Cl}_2]^+$ (diars = [1]) provides another example of a reversible redox couple for which

the spectropotentiostatic method has been applied.

[1] Diars

Figure 5 shows a thin-layer cyclic voltammogram for this system and **Figure 6** gives a series of spectra for a spectropotentiostatic experiment. Each spectrum was recorded 5 min after potential application so that $([\text{O}]/[\text{R}])_{\text{solution}}$ is at equilibrium with the electrode potential. Spectrum h is the oxidized form, whereas spectrum a is the reduced form. A Nernst plot from the spectra in **Figure 6** is shown in **Figure 7** ($E^0 = -0.091$ V vs SSCE, $n = 0.99$).

Polypyridylruthenium(II) Complexes

The prospect of developing new materials of relevance to the emerging field of molecular electronics, modelling electron-transfer processes in biological systems and

Figure 4 *In situ* UV-visible absorption spectra of 2.0 mM $\text{K}_3\text{Fe}(\text{CN})_6$ in aqueous 1 M KCl at a sequence of applied potentials vs Ag/AgCl: (a) 0.50 V, (b) 0.28 V, (c) 0.26 V, (d) 0.24 V, (e) 0.22 V, (f) 0.20 V, (g) 0.17 V and (h) 0.00 V. producing new electroactive and photoactive catalysts has led in years to considerable interest in transition metal polypyridyl complexes. Two examples of the application of the OTTLE spectroelectrochemical technique to the study of these fascinating systems are described here.

Identification of mixed-valence states in polynuclear polypyridylruthenium(II) complexes

Mixed-valence complexes provide an ideal way of studying electron transfer – the most fundamental process in chemistry – under controlled conditions. Polynuclear complexes containing polypyridylruthenium(II) moieties are of particular interest for the study of mixed valency because of their kinetic inertness in both the +II and +III oxidation states, generally reversible electrochemical behaviour, and good π -donor ability which allows interaction with bridging ligand orbitals. Spectroelectrochemical measurements can be used to probe electrogenerated mixed-valence states in such complexes. A good example (Table 1 and Figure 8)

Figure 5 Thin-layer cyclic voltammogram at 2 mV s^{-1} of $0.87 \text{ mM } [\text{Tc}^{\text{III}}(\text{diars})_2\text{Cl}_2]^+$, 0.5 M TEAP in DMF. (SSCE = Sodium chloride saturated calomel electrode.) is the controlled-potential oxidation of the [2, 2] species of the complex $[\{\text{Ru}(\text{bipy})_2\}_2(\mu\text{-OMe})_2][\text{PF}_6]_2$ in an OTTLE cell. Oxidation of the [2, 2] species to the mixed-valence [2,3] state results in the collapse of the metal-to-ligand charge transfer (m.l.c.t.) bands at 589 and 364 nm and the generation of a new transition at $\sim 1800 \text{ nm}$ ($\epsilon = 5000 \text{ dm}^3 \text{ mol}^{-1} \text{ cm}^{-1}$), which disappears on further oxidation to the Ru^{III} state. The observations that this transition is not solvato-chromic and that the half-width of the peak is much narrower than the value predicted from Hush theory for vectorial intervalence charge-transfer bands both point to a class III (Robin and Day fully delocalized) mixed-valence state.

Electronic properties of hydroquinone-containing ruthenium polypyridyl complexes

Ruthenium polypyridyl complexes bound to hydroquinone/quinone moieties are expected to yield information on the behaviour of hydroquinone-type compounds in biological processes. Furthermore, ruthenium(II)-hydroquinone complexes involving O and N bonds are likely to absorb well into the visible region and therefore have potential as dyes in sensitized

Figure 6 Spectra recorded during an OTTE spectropotentiostatic experiment on $0.87 \text{ mM } [\text{Tc}^{\text{III}}(\text{diars})_2\text{Cl}_2]^+$, 0.5 M TEAP in DMF . Applied potentials vs SSCE: (a) -0.250 V ; (b) -0.150 V ; (c) -0.100 V ; (d) -0.075 V ; (e) -0.050 V ; (f) -0.025 V ; (g) 0.100 V ; (h) 0.250 V . solar cells. A recent example in the application of spectroelectrochemistry to the study of hydroquinone-containing ruthenium polypyridyl complexes is the oxidation of $[\text{Ru}(\text{bipy})_2(\text{HL}^0)]^+$ ($\text{H}_2\text{L}^0 = 1,4\text{-dihydroxy-2,3-bis(pyrazol-1-yl)benzene}$) (Figure 9).

The spectral changes associated with the first two-electron oxidation step are reversible, and unstable long-lived intermediates are not present, as indicated by the clear isobestic points at 327, 398, 446 and 614 nm (Figure 9). After the first two-electron oxidation the m.l.c.t. band at 490 nm blue shifts to approximately 416 nm, and a new feature appears at 700 nm for $[\text{Ru}(\text{bipy})_2(\text{HL}^0)]^{2+}$. The presence of significant absorption features between 400 and 500 nm in the spectrum of the oxidized compound suggests that in the complex the metal centre is still in the ruthenium(II) state, consistent with interpretation from electrochemical data. The oxidized complex is therefore most likely the analogous ruthenium(II)–quinone species. After oxidation of the hydroquinone to quinone, the $\text{Ru}^{\text{II}} \rightarrow \text{bipy}(\pi_2^*)$ m.l.c.t. shifts to the blue as a result of the stabilization of the t_{2g} level when the σ -donating ability of the ligand is decreased. Further oxidation results in the irreversible loss of the

retinal, and vitamin B_{12} and its analogues. Two classic examples are presented here.

Vitamin B_{12}

Vitamin B_{12} (cyanocob(III)alamin) is an example of a quasi-reversible redox system that exhibits slow heterogeneous electron-transfer kinetics. Cyclic voltammetry alone suggests that the reduction of vitamin B_{12} is a single two-electron process at $E_{\text{pc}} = -0.93 \text{ V}$ vs SCE to the Co(I) redox state (**Figure 10a**). However, thin-layer spectroelectrochemistry using a Hg–Au minigrad OTTE in a spectropotentiostatic mode reveals that reduction takes place via two consecutive one-electron steps (**Figures 11 and 12**). **Figure 11** shows thin-layer spectra for the reduction to $\text{B}_{12}^{\cdot-}$, which occurs in the potential range -0.580 to -0.750 V , and **Figure 12** shows the spectral changes for the further reduction to B_{12}^{2-} , which occurs in the range -0.770 to -0.950 V . Nernst plots for these two reduction processes (using eqn [7] above) give values of $E_1 = -0.655 \text{ V}$, $n = 1$ and $E_2 = -0.880 \text{ V}$, $n = 1$, respectively. The two one-electron reduction processes are clearly shown by the plot of absorbance at 363 nm vs potential in **Figure 10b**, the first one-electron reduction occurring in a region with no apparent cathodic current (**Figure 10a**).

Figure 9 Spectroelectrochemical oxidation of $[\text{Ru}(\text{bipy})_2(\text{HL}^0)]^+$ ($\text{H}_2\text{L}^0 = 1,4\text{-dihydroxy-2,3-bis(pyrazol-1-yl)benzene}$) as a function of time between 0 and 20 min. Reprinted with permission from Keyes TE, Jayaweera PM, McGarvey JJ, and Vos JG (1997) *Journal of the Chemical Society, Dalton Transactions*, 1627–1632.

Cytochrome *c*

Often biological macromolecules will not undergo direct heterogeneous electron transfer with an electrode. Instead, mediator titrants are used that exchange electrons heterogeneously with the electrode and homogeneously with the macromolecules. **Figure 13** gives spectra obtained for the reduction of a mixture of the haem proteins cytochrome *c* and cytochrome *c* oxidase, both initially in the fully oxidized state.

Each spectrum was recorded after the coulometric addition of 5×10^{-9} equivalents of reductant, the methyl viologen radical cation ($\text{MV}^{\cdot+}$) electrogenerated at a SnO_2 OTE. The reaction sequence is an EC catalytic regeneration mechanism:

In solution, one $\text{MV}^{\cdot+}$ species can reduce a single haem site in cytochrome *c* or one of two in the oxidase.

Figure 10 (a) Thin-layer cyclic voltammogram of 1 mM vitamin B₁₂, Britton–Robinson buffer pH 6.86, 0.5 M Na₂SO₄. (b) Plot of absorbance at 368 nm vs potential, recorded at effectively $\sim 0.003 \text{ mV s}^{-1}$, from spectra in **Figures 11** and **12**. Reprinted by courtesy of Marcel-Dekker, Inc. from Heineman WR, Hawkridge FM, and Blount HN (1984) Spectroelectrochemistry at optically transparent electrodes. II. Electrodes under thin-layer and semi-infinite diffusion conditions and indirect coulometric titrations. In: Bard AJ (ed.) *Electroanalytical Chemistry. A Series of Advances*, vol 13, pp. 1–113. New York: Marcel-Dekker.

The absorbance increase (**Figure 13**) at 605 nm corresponds to the reduction of the two haem components of cytochrome *c* oxidase; the increase at 550 nm corresponds to the reduction of the haem in cytochrome *c*. Study of plots of absorbance change vs coulometric charge (see inset of **Figure 13**) indicates that $\text{MV}^{\bullet+}$ initially reduces one of the haem groups in cytochrome *c* oxidase, then the haem in cytochrome *c*, before it reduces the second haem of the oxidase.

Modified Electrodes

Immobilization of chemical microstructures onto electrode surfaces has been a major growth area in electrochemistry in recent years. Compared to conventional electrodes, greater control of electrode characteristics

Figure 11 Thin-layer spectra for reduction of vitamin B₁₂ to B_{12r} in a solution of 1 mM vitamin B₁₂, Britton–Robinson buffer pH 6.86, 0.5 M Na₂SO₄. To obtain the spectra, the potential was stepped in 0.5 mV increments and maintained at each step for 3–5 min until spectral changes ceased. Applied potentials vs SCE: (a) -0.550 V ; (b) -0.630 V ; (c) -0.660 V ; (d) -0.690 V ; (e) -0.720 V ; (f) -0.770 V . the field of molecular electronics and electrochemical sensors with high selectivity and sensitivity.

Spectroelectrochemical measurements, both *ex situ* and *in situ*, are frequently used in the characterization of modified electrodes. In the case of *in situ* spectroelectrochemical measurements, the modified electrode can be considered to be analogous to an OTTLE, the redox active layer being physically or chemically confined to the electrode surface. Electronic spectroelectrochemistry sees significant use in the study of electrodes modified with electrochromic surface films, for which some examples are given below.

Characterization of Electrochromic Materials

Chemical species that can be electrochemically switched between different colours are said to be electrochromic.

Electrochromism results from the generation of different visible-region electronic absorption bands on switching between redox states. The colour change is commonly between a transparent ('bleached') state and a coloured state, or between two coloured states. In cases where more than two redox states are electrochemically available, the electrochromic material may exhibit several colours and be termed polyelectrochromic. Likely applications of electrochromic materials include their use in controllable light-reflective or light-transmissive devices for optical information and storage, antiglare car rear-view mirrors, sunglasses, protective eyewear for the military, controllable aircraft canopies, glare-reduction systems for offices, and 'smart windows' for use in cars and in buildings.

Prussian blue

Prussian blue (PB; iron(III) hexacyanoferrate(II)) thin films can be switched to Prussian white (PW) on electrochemical reduction and to Prussian yellow (PX) on oxidation via the partially oxidized Prussian green (PG). For all these electrochromic redox reactions, there is concomitant ion ingress/egress in the films for electro-neutrality. The spectra of PX, PG, PB and PW are shown in **Figure 14**, together with two intermediate states between blue and green. The intense blue colour in the $[\text{Fe}^{\text{III}}\text{Fe}^{\text{II}}(\text{CN})_6]^-$ chromophore of PB is due to an intervalence charge-transfer (CT) absorption band centred at 690 nm. The yellow absorption band in PX corresponds with that of $[\text{Fe}^{\text{III}}\text{Fe}^{\text{III}}(\text{CN})_6]$ in solution, both maxima ($\lambda_{\text{max}} = 425$ nm) coinciding with the

(weaker) $[\text{Fe}^{\text{III}}(\text{CN})_6]^{3-}$ absorption maximum. On increase from +0.50 V vs SCE to more oxidizing potentials, the original PB peak shifts continuously to longer wavelengths with diminishing absorption, while the peak at 425 nm steadily increases, owing to the increasing $[\text{Fe}^{\text{III}}\text{Fe}^{\text{III}}(\text{CN})_6]$ absorption. The reduction of PB to PW is by contrast abrupt, with transformation to all PW or all PB without pause, depending on the potential that is set. In the cyclic voltammogram of a PB-modified electrode, the broad peak for $\text{PB} \rightleftharpoons \text{PX}$ in contrast with the sharp $\text{PB} \rightleftharpoons \text{PW}$ transition emphasizes the range of compositions involved. This difference in behaviour, supported by ellipsometric measurements, indicates continuous mixed-valence compositions over the blue-to-yellow range in contrast with the presumably immiscible PB and PW, which clearly transform one into the other without intermediacy of composition.

Conducting polymers

Chemical or electrochemical oxidation of numerous resonance-stabilized aromatic molecules including pyrrole, thiophene, aniline, furan, carbazole, azulene and indole produces electronically conducting polymers. In their oxidized forms, such conducting polymers are 'doped' with counteranions (*p*-doping) and possess a delocalized π electron band structure, the energy gap between the highest occupied π electron band (valence band) and the lowest unoccupied band (the conduction band) determining the intrinsic optical properties of these materials. The doping process (oxidation) introduces polarons (in polypyrrole, for example, these are radical cations delocalized over ca. four monomer units), which are the major charge-carriers. Reduction of conducting polymers with concurrent counteranion exit removes the electronic conjugation, to give the 'undoped' (neutral) electrically insulating form.

All conducting polymers are potentially electrochromic in thin-film form, redox switching giving rise to new optical absorption bands in accompaniment with transfer of electrons/counteranions. Good examples are the polymers of aniline, *o*-toluidine and *m*-toluidine, which are easily prepared as thin films by electrochemical oxidation from aqueous acid solutions of the appropriate monomer. The electrical and electrochromic properties of such polyanilines depend not only on oxidation state but also on the protonation state, and polyanilines are in fact polyelectrochromic (transparent yellow to green to dark blue to black), the yellow-green transition being durable to repetitive colour switching. Spectra for a poly(*m*-toluidine)-modified electrode are illustrated in Figure 15.

The two low-wavelength spectral bands observed are assigned to an aromatic $\pi-\pi^*$ transition (≤ 330 nm) related to the extent of conjugation between the adjacent

rings in the polymer chain, and to radical cations formed in the polymer matrix (≤ 440 nm). With an increase in applied potential, the ≤ 330 nm band absorbance decreases and the ≤ 440 nm increases (Figure 15), the isobestic point indicating that the two species have the same chemical stoichiometry with differences only in electron(s). Beyond +0.30 V, the conducting region is entered; the ≤ 440 nm band decreases as a broad free carrier electron band ~ 800 nm is introduced. Response times for the yellow-green transition following a potential step can be determined using a diode array spectrophotometer (Figure 16).

Viologens in Nafion

In addition to being important mediator titrants, 1,1'-disubstituted-4,4'-bipyridiliums (viologens) are a major group of electrochromic materials. Electrochromism occurs in bipyridiliums because, in contrast to the bipyridilium dications, the radical cations formed on

Figure 17 Spectra recorded at -0.90 V vs SCE during the 2nd, 4th, 6th, 8th and 10th cyclic voltammograms for an ITO/Nafion electrode in 0.1 mM 1,1'-dimethyl-4,4'-bipyridilium dichloride + 0.2 M KCl (pH 5.5). The vertical arrows indicate absorbance increase with scan number. For a comparable experiment in the absence of Nafion, the maximum absorbance was <0.01 . Figure 18 (a) Spectra recorded at $t = 0, 10, 20, 30, 40$ and 50 s in response to a potential step from $+1.00$ to -0.90 V vs SCE for an ITO/Nafion/1,1'-di-*n*-hexyl-4,4'-bipyridilium electrode in 0.1 mM 1,1'-di-*n*-hexyl-4,4'-bipyridilium dibromide $+0.2$ M KCl (pH 5.5). The vertical arrows indicate absorbance increase with time. (b) Spectra recorded at $t = 0, 10, 20, 30, 40$ and 50 s in response to a potential step from -0.90 to $+1.00$ V vs SCE for an ITO/Nafion/1,1'-di-*n*-hexyl-4,4'-bipyridilium electrode in 0.1 mM 1,1'-di-*n*-hexyl-4,4'-bipyridilium dibromide $+0.2$ M KCl (pH 5.5). The vertical arrows indicate absorbance decrease with time. Reproduced with permission from Mortimer RJ and Dillingham JL (1997) *Journal of the Electrochemical Society* 144: 1549–1553.

electroreduction have a delocalized positive charge, coloration arising from an intramolecular electronic transition. Suitable choice of nitrogen substituents to attain the appropriate molecular orbital energy levels can, in principle, allow colour choice of the radical cation. For short alkyl chain length, 1,1'-dialkyl-4,4'-bipyridiliums, both the dication and radical-cation states, are soluble in water and any electrochromic device (ECD) using such bipyridiliums would have the limitation of a low write–erase efficiency. One solution to this problem involves electrostatic binding of bipyridilium dications into anionic polyelectrolyte films. When a Nafion-modified electrode is immersed in an aqueous solution of 1,1'-dialkyl-4,4'-bipyridilium (alkyl = methyl, ethyl, *n*-propyl, *n*-butyl, *n*-pentyl, *n*-hexyl), the 1,1'-dialkyl-4,4'-bipyridilium accumulates in the anionic polyelectrolyte such that its concentration is considerably higher than that in the bulk solution. **Figure 17** illustrates the uptake of 1,1'-dimethyl-4,4'-bipyridilium into a Nafion film

monitored by *in situ* spectral measurements. The coloured form in each case is purple, from the presence of monomeric (blue, λ_{max} 600 nm) and dimeric (red, λ_{max} 500 nm) viologen radical cations. For such viologen-incorporated Nafion films, the electrochromic response times are in excess of 60 s for both coloration and bleaching and independent of viologen size. **Figure 18** shows absorbance spectra measured every 10 s in response to a potential step between the oxidized and reduced forms, for the case of the 1,1'-di-*n*-hexyl-4,4'-bipyridilium system. The longer response time for the oxidation (bleaching) reflects the slower diffusion of radical-cation dimers through the Nafion film compared to that of the monomeric radical cations.

Five-colour polyelectrochromicity, by application of an outer Nafion layer (with subsequent electrostatic incorporation of the methyl viologen system) to an inner layer of PB, is possible (**Figure 19**). The transparent/purple viologen dication/radical cation electrochromicity

Figure 19 Spectra recorded at +0.50 V (blue), –0.20 V (transparent) and –0.90 V (purple) vs SCE for an ITO/PB/Nafion/methyl viologen electrode in 0.1 mM 1,1'-dimethyl-4,4'-bipyridilium dichloride + 0.2 M KCl (pH 5.5). Reproduced with permission from Mortimer RJ and Dillingham JL (1997) *Journal of the Electrochemical Society* 144: 1549–1553.

operates in the potential region where the PB is in its (reduced) transparent state; the bilayer electrode system thus exhibits yellow/green/blue/transparent/purple colours.

Introduction

Spectroelectrochemistry encompasses a group of techniques that allow simultaneous acquisition of electrochemical and spectroscopic information *in situ* in an electrochemical cell. A wide range of spectroscopic techniques may be combined with electrochemistry, including electronic (UV-visible) absorption and reflectance spectroscopy, luminescence spectroscopy, infrared and Raman spectroscopies, electron paramagnetic resonance spectroscopy and ellipsometry. Molecular properties such as molar absorption coefficients, vibrational absorption frequencies and electronic or magnetic resonance frequencies, in addition to electrical parameters such as current, voltage or charge, are now being used routinely for the study of electron transfer reaction pathways and the fundamental molecular states at interfaces. In this article the principles and practice of electronic spectroelectrochemistry are introduced.

Cell Design

In electronic UV-visible spectroelectrochemistry an optical beam traverses an optically transparent electrode

(OTE) in one of the three configurations shown in Figure 1.

In transmission spectroelectrochemistry the optical beam is directed perpendicularly through the OTE and the adjacent solution either under semi-infinite linear diffusion conditions (Figure 1a) or in a thin-layer cell where diffusion is restricted (Figure 1b). Internal reflection spectroscopy (IRS) involves introducing the optical beam through the rear side of an OTE at an angle greater than the critical angle so that the beam is totally reflected (Figure 1c). In IRS spectral changes are observable owing to the small penetration of the electric field vector into the solution. Both transmission and reflection spectroscopy have been coupled with numerous electrochemical excitation signals to generate a variety of spectro-electrochemical techniques.

Optically Transparent Electrodes

As the working electrode in a spectroelectrochemical experiment, an OTE needs to have both wide optical and potential 'windows', a sufficiently low resistance for good electrode potential control, good stability and surface reproducibility. Table 1 summarizes the optical and resistance data of some OTEs which are typically thin conducting films on substrate surfaces or minigrids (electroformed mesh).

Thin Conducting Films

Any conductor becomes transparent if it is made sufficiently thin, and in OTE design a compromise is usually made between resistance and transmission values (Table 1). Most OTEs are prepared by vapour deposition or cold sputtering of a thin film of metal such as platinum or gold or a 'doped' oxide such as tin oxide (Nesa) or indium oxide (Nesatron) on a transparent substrate such as glass, quartz or plastic. OTEs based on thin conducting films were first introduced in 1964 with the use of an antimony-doped tin oxide film on a glass substrate (Nesa glass) in a transmission spectroelectrochemical study of the electrooxidation of *o*-toluidine. Tin-doped indium oxide (ITO) is presently the most common conducting film used for UV-visible spectroelectrochemical studies.

The 'doped' semiconductor oxides, as used in liquid-crystal displays, are particularly attractive owing to their wide potential window (+1.2 to –0.6 V vs saturated calomel electrode (SCE)) between solvent oxidation and reduction. Furthermore, the absence of surface oxidation/reduction currents (since these surfaces are already oxidized) is another advantage over platinum and gold OTEs. Figure 2 shows typical spectra of n-type tin oxide films on various substrates. The optical absorption by the free carriers in the 'doped' tin oxide is in the infrared region, giving transparency in the visible region. Film thickness can be accurately calculated from the interference patterns that are observed in the spectra.

Minigrids

Minigrid electrodes consist of electroformed wire mesh (40–800 wires cm^{-1}) of Au, Pt, Ni, Ag or Cu. The light is

Figure 2 Transmission spectra of SnO_2 coatings on various substrates: (curve a) glass, $3 \Omega \text{ sq}^{-1}$; (curve b) Vicor, $6 \Omega \text{ sq}^{-1}$; (curve c) quartz, $20 \Omega \text{ sq}^{-1}$. Reprinted by courtesy of Marcel Dekker, Inc. from Kuwana T and Winograd N (1974) Spectroelectrochemistry at optically transparent electrodes. I. Electrodes under semi-infinite diffusion conditions. transmitted through the microscopic holes between the wires of the minigrid, which in operation functions as a planar electrode after electrolysis has proceeded for sufficient time that the diffusion layer depth becomes large compared to the wire and hole dimensions. The minigrid transmittance varies from 22 to 82%, depending upon the number of wires per centimetre. Since light passes through the holes in the minigrid, the optical window is essentially unlimited. The electrochemical properties of the gold minigrid are similar to those of the gold film OTE. The negative potential limit of gold and nickel minigrids can be extended by around 0.4 V by deposition of a thin mercury film, which has a high overpotential to hydrogen evolution.

Transmission Spectroelectrochemical Cells

Two types of cell geometry can be defined on the basis of the electrolyte solution thickness adjacent to the electrode (Figure 1a and Figure 1b).

Semi-infinite Linear Diffusion Conditions

The rate of an electrochemical process depends not only on electrode kinetics but also on the transport of species to/from the bulk solution. Mass transport can occur by diffusion, convection or migration. Generally, in a spectroelectrochemical experiment, conditions are chosen in which migration and convection effects are negligible. The solution of diffusion equations, that is the discovery of an equation for the calculation of oxidized form [O] and reduced form [R] concentrations as functions of distance from electrode and time, requires boundary conditions to be assumed. Usually the electrochemical cell is so large relative to the length of the diffusion path

that effects at walls of the cell are not felt at the electrode. For semi-infinite linear diffusion boundary conditions, one can assume that at large distances from the electrode the concentration reaches a constant value.

Semi-infinite Linear Diffusion Spectroelectrochemical Cells

In the semi-infinite linear diffusion spectroelectrochemical cell geometry (Figure 1a), the cell is analogous to a conventional electrochemical cell, the electrode being in contact with solution much thicker than the diffusion layer adjacent to the electrode. Semi-infinite linear diffusion spectroelectrochemical cell design requires that electrolysis products generated at the counterelectrode should not interfere with the absorbance measurement and that complete deoxygenation should be easily achieved. Figure 3 shows the classic sandwich-cell design, with a thin film OTE as the working electrode. The reference electrode and counterelectrode and the side arms for degassing are positioned so that the cell may be placed with the surface of the OTE in a horizontal plane. A Luggin capillary places the reference electrode near to the surface of the OTE for minimization of solution resistance in the control of the working electrode potential.

These cells are normally used for experiments (chronoamperometry and chronocoulometry) in which large-amplitude steps are applied in order to carry out an electrolysis in the diffusion region. For the case of a general reduction reaction,

Figure 3 Sandwich cell for transmission measurement under semi-infinite linear diffusion conditions. Reprinted by courtesy of Marcel-Dekker, Inc. from Kuwana T and Winograd N (1974) Spectroelectrochemistry at optically transparent electrodes. I. Electrodes under semi-infinite diffusion conditions. In: Bard AJ (ed.) *Electroanalytical Chemistry. A Series of Advances*, vol. 7, pp. 1–78. New York: Marcel-Dekker.

the absorbance change can be described by considering a segment of solution of thickness dx and cross-sectional area A_{elec} (Figure 4). If species R of molar absorption coefficient, ϵ_R , is the only species absorbing at the monitored wavelength, then the differential absorbance upon passage of light through this segment is

$$dA = \epsilon_R [R](x, t) dx \quad [2]$$

The total absorbance is then

$$A = \epsilon_R \int_0^{\infty} [R](x, t) dx \quad [3]$$

If R is a stable species, the integral in eqn [3] is the total amount of R produced per unit area and is equal to Q/nFA_{elec} , where Q is the charge passed in electrolysis, n is the number of electrons and F is the Faraday constant. Since Q is given by the integrated Cottrell equation, which describes the chronoamperometric response,

$$Q = \frac{2nF A_{\text{elec}} [O] D_O^{1/2} t^{1/2}}{\pi^{1/2}} \quad [4]$$

we have

$$A = \frac{2\epsilon_R [O] D_O^{1/2} t^{1/2}}{\pi^{1/2}} \quad [5]$$

which shows that the absorbance should be linear with $t^{1/2}$. Analysis of the slopes of A vs $t^{1/2}$ plots are useful in mechanistic studies where coupled homogeneous reactions follow the initial electrode reaction.

Optically Transparent Thin-Layer Electrochemical Cells

The optically transparent thin-layer electrode (OTTLE) cell, first reported in 1967, consists of a sandwich structure with a minigrad OTE working electrode (Figure 5). The assembly is placed in a cup of solution containing both the counterelectrode and reference electrode and is filled either by capillary action or by applying nitrogen pressure to give a thin (<0.2 mm) solution layer confined next to the OTE. These cells can easily be constructed in

Figure 4 Schematic view of the experimental arrangement for transmission spectroelectrochemistry.

Figure 5 Optically transparent thin-layer electrode (OTTLE) cell: (a) front view; (b) side view. the laboratory using ordinary microscopy slides, 100 μm Teflon adhesive tape spacers, a minigrid and epoxy resin.

A large ohmic potential drop is often present in OTTLE cells owing to the nonuniform current distribution within the thin-layer cavity caused by the large distance between the working electrode and counterelectrode. This is not a problem, as experiments generally involve exhaustive electrolyses, where any ohmic drop can be 'out-waited'. The OTTLE cell design enables the techniques of thin-layer electrochemistry, cyclic voltammetry, controlled potential coulometry and UV-visible spectroscopy to be performed in one unified experiment using a small quantity of solution.

Spectropotentiostatic Measurements with an OTTLE Cell

Determination of E^0 , the reversible electrode potential, and n , the number of electrons in a redox reactions, can be performed in a sequence of spectropotentiostatic measurements with an OTTLE cell. Generally, for the reversible system given in eqn [1], the $[O]/[R]$ ratio at the electrode surface is controlled by the applied potential according to the Nernst equation:

$$E_{\text{applied}} = E^0 + \frac{RT}{nF} \ln \left(\frac{[O]}{[R]} \right)_{\text{surface}} \quad [6]$$

In an OTTLE cell, on application of a new potential, the concentration of O and R in solution is quickly adjusted

to the same values as those existing at the electrode surface, giving at equilibrium:

$$\left(\frac{[O]}{[R]} \right)_{\text{surface}} = \left(\frac{[O]}{[R]} \right)_{\text{solution}} \quad [7]$$

The Nernst equation is a thin-layer cell that can then be generally expressed as

$$E_{\text{applied}} = E^0 + \frac{RT}{nF} \ln \left(\frac{[O]}{[R]} \right) \quad [8]$$

In order to obtain E^0 and n values, a series of potentials are sequentially applied to the thin-layer cell containing a test solution. The redox couple is incrementally converted from one oxidation state into another by the applied potentials, resulting in different ratios of $[O]/[R]$ that can be determined spectrally. Each applied potential is maintained until electrolysis ceases, so that the equilibrium value of $[O]/[R]$ is established as defined by the Nernst equation. The E^0 and n values can then be obtained by a Nernst plot made by the values of E_{applied} and the corresponding ratios of $[O]/[R]$. In practice, the range of applied potentials is selected to span E^0 of the redox couple, so that spectra for complete reduction/oxidation and intermediate values of $[O]/[R]$ can be obtained. Selecting a wavelength (usually the maximum wavelength) of O as the monitoring wavelength, for example, the ratio $[O]/[R]$ determined by recording the *in situ* absorbance changes at a certain applied potential is produced using the Beer–Lambert law,

$$\frac{[O]}{[R]} = \frac{(A_i - A_R)/\Delta\epsilon b}{(A_O - A_i)/\Delta\epsilon b} = \frac{(A_i - A_R)}{(A_O - A_i)} \quad [9]$$

where A_R is the absorbance of the reduced form, A_O is the absorbance of the oxidized form, A_i is the absorbance obtained at an intermediate applied potential, $\Delta\epsilon$ is the difference in molar absorptivity between O and R at the selected wavelength and b is the light path length in the thin-layer cell. Substituting eqn [9] into eqn [8], the Nernst equation expressed by absorbance is obtained:

$$E_{\text{applied}} = E^0 + \frac{RT}{nF} \ln \frac{(A_i - A_R)}{(A_O - A_i)} \quad [10]$$

The intercept and slope of the straight line of E_{applied} vs $\ln(A_i - A_R)/(A_O - A_i)$ then give E^0 and n , respectively. Values of E^0 and n for numerous reversible redox couples in aqueous, nonaqueous and molten salt solvents have been determined from Nernst plots of such spectropotentiostatic experiments.

Spectroelectrochemical Cells for Modified Electrode Studies

Immobilization of chemical microstructures onto electrode surfaces has been a major growth area in electrochemistry. In their characterization using *in situ* UV-visible absorption spectroelectrochemical measurements, a modified electrode can be considered to be analogous to an OTTE, the redox active layer being physically or chemically confined to the electrode surface. Spectroelectrochemical cell design is often simple, a rectangle of OTE being mounted transverse to the optical beam direction in a conventional 1 cm cuvette. The counterelectrode, placed opposite the working electrode, is typically a loop of platinum wire through which the light beam can pass. A machined polytetraethylene lid with appropriate holes is used to hold the Luggin capillary from the reference electrode above the light path and the working electrode and counterelectrode in place.

Internal Reflection Spectroelectrochemical Cells

A typical cell configuration is shown in Figure 6. This cell has most of the electrode area masked and exposes only the region where the light beam is incident to the

electrode–solution interface. The cell shown allows for five reflections, but the number can be selected for the requirements of the experiment.

Electrochemical Control and Techniques

Modern electrochemical research encompasses a wide range of techniques, including those based on potential sweep, potential or current step, use of hydrodynamic electrodes, impedance measurements and electrolysis. Electrode processes are investigated at the working electrode, under potentiostatic or galvanostatic control, with a counterelectrode being used to complete the electrical circuit. Historically, in controlled potential experiments, the counterelectrode was also the reference electrode, with the double function of passing current and acting as a reference potential for controlling the potential of the working electrode. Nowadays, three-electrode systems are routinely used where the current passes from the working electrode to a counterelectrode (of larger area than the working electrode), the separate reference electrode serving purely as a reference potential and not passing current. Voltammetric, step and coulometric methods are the most frequently used electrochemical techniques in UV-visible spectroelectrochemistry.

Voltammetric Methods

Electrochemical techniques in which a potential is imposed upon an electrochemical cell and the resulting current is measured are termed voltammetric methods. Numerous methods have been developed, with variation in the type of potential waveform impressed on the cell, the type of electrode used and the state of the solution in the cell (quiescent or flowing). Voltammetry has proved to be very useful for analysing dilute solutions, both quantitatively and qualitatively, for inorganic, organic and biological components, measuring thermodynamic parameters for redox systems, and studying the kinetics of coupled homogeneous chemical reactions. In spectroelectrochemistry, linear-sweep and cyclic voltammetric methods are generally used in quiescent solutions. In linear-sweep voltammetry, for the general redox reaction in eqn [1] above, the potential of the working electrode is swept from a value E_1 , at which O cannot undergo reduction, to a potential E_2 , at which the electron transfer is driven rapidly. In cyclic voltammetry, a triangular waveform is applied; once the potential reaches E_2 , the direction of the sweep is reversed and the electrode potential is scanned back to E_1 .

Potentiostatic Control

The heart of modern electrochemical instrumentation is the potentiostat, which has control of the voltage across

the working electrode–counterelectrode pair; it adjusts this voltage in order to maintain the potential difference between the working and reference electrodes (which it senses through a high-impedance feedback loop) in accord with the programme supplied by a function generator. The instrumentation requirements for thin-layer spectroelectrochemistry are not as exacting or expensive as some other types of spectroelectrochemistry. Since the large ohmic potential drop precludes very fast measurements, relatively inexpensive (slow) potentiostats with a good digital voltmeter are usually adequate.

Step Techniques

In step techniques, a potential or current step is instantaneously applied to the working electrode. Following this perturbation to the electrochemical system, current, charge or potential is monitored versus time.

Chronoamperometry

Chronoamperometry involves the study of the variation of the current response with time under potentiostatic control. Generally the working electrode is stepped from a potential at which there is no electrode reaction to one corresponding to the mass-transport-limited current, and the resulting current–time transient is recorded. In double-step chronoamperometry, a second step inverts the electrode reaction and this method is useful in analysing cases where the product of the initial electrode reaction is consumed in solution by a coupled homogeneous chemical reaction.

Chronocoulometry

Chronocoulometry is similar to chronoamperometry except that the current is integrated and the variation of charge with time is studied. The advantages of integration are that the signal increases with time, facilitating measurements towards the end of the transient, when the current is almost zero; integration is effective in reducing signal noise; it is relatively easy to separate the capacitive charge from the faradaic charge.

In an OTTLE cell, coulometry is generally performed by application of a potential that causes complete electrolysis of the electroactive species. Electronic integration of the resulting current gives the total charge consumed by the electrode process, which can be related to the number of moles and electrons involved in the redox reaction by Faraday's law. It is important to carry out a second experiment in the absence of the electroactive species, to allow subtraction of the 'blank' charge for charging of the electrode/electrolyte interface and any background redox reactions involving the solvent and electrode.

Chronopotentiometry

Generally constant-current chronopotentiometry is employed, in which the constant current applied to the working electrode causes the electroactive species to be reduced at a constant rate. The potential of the electrode moves to values characteristic of the redox couple and varies with time as the $[O]/[R]$ concentration ratio changes at the electrode surface. In the case of a reduction, after the concentration of O drops to zero at the electrode surface, the flux of O becomes insufficient to accept all the electrons being forced across the electrode–electrolyte interface. The potential, at this transition time, then rapidly changes towards more negative values until a new, second reduction can start.

Spectroscopic Measurements

UV-visible spectral measurements under electrochemical control can often be made using a conventional spectrometer. For thin-layer spectroelectrochemistry experiments, a sufficiently large sample spectrometer compartment is required to accommodate the OTTLE cell.

Rapid Scan and Diode Array Spectrometers

For kinetic measurements, analysis of complete time-resolved spectra is possible using a rapid-scan spectrometer

Figure 7 Block diagram of typical apparatus for reflectance spectroscopy. Reprinted with permission from Robinson J (1984) Spectroelectrochemistry. *Electrochemistry Specialist Periodical Reports*, vol. 9, pp. 101–161. London: Royal Society of Chemistry.

(RSS) interfaced with a microcomputer. With an RSS it is possible to record a 1000-point 450 nm wide spectrum in the range 240–800 nm in about 5 ms, although signal averaging is generally necessary to obtain the required sensitivity. Although RSS instruments have been employed extensively and with great success, the instrumental design is now obsolete and usually instruments are used that employ diode arrays in combination with a polychromator. In these ‘optical multichannel analysers’, the whole spectrum is spatially dispersed by a polychromator and then imaged onto the detector, which consists of an array of tiny photodiodes.

Reflectance Spectroscopy Measurements

A schematic diagram of the typical apparatus required for reflectance spectroscopy is given in **Figure 7**. The optical components consist of a highly stabilized intense light source, frequently a mercury or mercury/xenon arc, a monochromator, a polarizer, the electrochemical system, a photodetector (photomultiplier or photodiode) and appropriate collimating and focusing lenses. The electrode potential is periodically modulated by either a square or a sinusoidal waveform and the small changes in reflectivity so caused are detected with a lock-in amplifier. For kinetic measurements where the shape of the reflectance–time transient is required, the lock-in amplifier is replaced with a signal averager. The requirements for the cell and electrode design are identical to those of ellipsometry.

Introduction: Historical Overview

Pharmaceutical research and production, the terms used today, began between the 1920s and 1930s, around the same time when the classical branches of spectroscopy, ultraviolet (UV) and infrared (IR) spectroscopies, became broadly available for the scientific and analytical communities. This created a solid ground for the wide application of the above-mentioned techniques in drug research and quality control. The presentation of UV and IR data became an important part of the characterization of (potential) drug materials. During these years, the application of spectrophotometry for the quantitative analysis of bulk drugs and drug formulations was mainly based on transforming them into colored derivatives, followed by colorimetric measurements; as of the 1940s, measurements based on native UV spectra also started to spread.

The invention and rapid proliferation of nuclear magnetic resonance (NMR) and organic mass spectrometry (MS) by the 1960s created an entirely new situation in drug research. NMR and MS not only became indispensable tools for the structure elucidation

of potential drugs, the intermediates in their synthesis, and their impurities, but they also became critically important in their own right in various drug-design strategies, the characterization of drug–receptor interactions, and metabolite identification. To this day, the role of NMR and MS keeps increasing with the continuously improving capabilities of these techniques.

In the quality control of drugs, UV spectrophotometry – although its importance is decreasing – is still one of the most widely used methods for the assay of bulk drugs and drug formulations. IR and near-infrared (NIR) spectroscopies are important methods for the rapid identification of drugs, whereas atomic spectroscopy plays a fairly important role in the determination of metal impurities.

The coupling of spectroscopic techniques with separation (mainly chromatographic) methods has led to extremely powerful methods for both drug research and quality control. High-performance liquid chromatography (HPLC) coupled with UV and especially MS became indispensable tools both in structure elucidation and in quantitative analysis of drugs, impurities, and metabolites in various matrices. Since the pharmaceutical industry is one of the most important markets for these instruments, the directions of their further development are greatly influenced by the requirements of the pharmaceutical research, industry, and drug registration agencies.

Spectroscopic and Spectrophotometric Methods in Drug Quality Control

Spectroscopic and Spectrophotometric Methods in Pharmacopoeias

General chapters in the modern pharmacopoeias (*European Pharmacopoeia*, *United States Pharmacopoeia*, *Japanese Pharmacopoeia*, etc.) contain brief summaries of the theory and practice of the molecular and atomic spectroscopic techniques used in the quality control of drugs and drug formulations. The role of the individual spectroscopic techniques in the monographs of these is summarized as follows.

UV spectrophotometry has a double role in modern pharmacopoeias. The less important role is the identification of bulk drugs and the active ingredients in their formulations. More important is its use for their assay, that is, determination of the active ingredient content (requirement usually minimum 98–99% and ± 5 to 10%

of the labeled amount, respectively). Although it is a nonspecific method, and for this reason its importance is slowly decreasing, its share among the assay methods is still around 10%. Outdated color reactions are disappearing from both the qualitative and quantitative analyses. The most frequently appearing method in the various monographs for assay and purity control purposes is HPLC. It has to be mentioned that in the overwhelming majority of cases the detector is an UV spectrophotometer.

The most important field of application of IR spectroscopy in pharmacopoeias is the identification of drug materials by comparing their spectra with those of reference standards using mainly the potassium bromide pellet technique. In some cases, the reason for obtaining not completely identical spectra can be polymorphism. If this is known not to affect the therapeutic value of the drug, the test sample and reference standard are dissolved in the same volatile solvent, and after evaporation of the solvent the spectra are compared again.

Optical rotatory power (measured usually at the sodium D line at 589 nm) is among the physical constants determined in the case of chiral drugs administered as the pure enantiomer, with circular dichroism spectroscopy providing an enhanced characterization of chiral drugs.

NMR spectroscopy is used in pharmacopoeias for identification purposes in a very limited number of cases only.

Although the most generally used limit test for heavy metals is still based on their classical test-tube reaction with sulfide ion, atomic absorption spectrometry is increasingly used if the aim is the selective determination of traces (usually 2–20 ppm) of individual metals, for example, zinc in acetylcysteine; iron in ascorbic acid; palladium in acitrecin; cadmium, chromium, lead, mercury, nickel, and zinc in ferrous fumarate; and so on. Atomic emission spectrometry (AES) and inductively coupled plasma atomic emission spectrometry (ICP-AES) are very seldom used, for example, for the determination of potassium impurity in sodium chloride and boron (maximum 1 ppm) in dalteparin sodium.

Spectroscopic and Spectrophotometric Methods in the Practice of Drug Quality Control

The main aim of quality control is to contribute to the safety of drug therapy by assuring that

- the pharmaceutical product contains the labeled amount of the active ingredient;
- the bulk drug material and formulations made thereof contain limited amounts of impurities (related organic impurities and degradation products, inorganic impurities and residual solvents, etc.);
- the bioavailability of the active ingredient in the formulation is under control.

In the course of everyday practice of pharmaceutical analysis (especially in the case of new drugs), the armory of the applied methods is wider and the requirements stricter than in the pharmacopoeias.

As already mentioned, IR spectroscopy is the most widely used method for the identification of bulk drugs. NIR spectroscopy has become an important method especially in the in-process control of the production of solid dosage forms. With the aid of the fiber optics in the reflection mode, this technique is suitable for the identification, moreover quantitative determination, of the components of a solid dosage form even within blister package form.

The importance of UV spectrophotometry for the assay of bulk drug materials and pharmaceutical formulations is decreasing more rapidly than reflected by the pharmacopoeias. The reason for this is the poor selectivity of this method. Since in the majority of cases the impurities and degradation products have the same or very similar chromophoric system as the drug material, these are usually measured together with the latter. This is illustrated in **Figure 1** using prednisolone as an example. As it is seen, all six impurities contain the same α , β -unsaturated oxo moiety and for this reason their spectra are very similar: they are measured together with prednisolone around 243 nm. The preferred selective and stability-indicating method for the assay of bulk drug materials is HPLC (with a UV detector). However, UV spectrophotometry can still be successfully used in such instances when the selectivity is not an important prerequisite, for example, in the dissolution testing of some of the solid dosage forms, such as just prednisolone tablets.

Of the above-mentioned three main groups of impurities in drug materials, spectroscopic methods are not involved in the determination of residual solvents. The increasing importance of atomic spectroscopic methods for the determination of traces of metals and semimetals has already been mentioned.

Owing to their potential adverse effects and hence potential contribution to the side effect profile of drugs, controlling related organic impurities is the most important task in drug quality control. Their determination at the order of magnitude of 0.01–0.1% requires highly selective and sensitive methods. In the majority of cases this is HPLC with UV detector. If the structure of the impurity is unknown (this is the general situation in the pharmacopoeias), the quantity of the impurity can only be expressed relative to the main component, based on the presumption that their UV absorbances at the wavelength of the detection are identical. However, for a less UV-active impurity in a strongly UV-active drug this can lead to underestimation of the impurity; conversely, a strongly UV-active impurity will be overestimated in a poorly UV-active drug

Figure 1 Diode-array UV spectra of prednisolone and its related impurities. Reprinted from Görög S, Babják M, Balogh G, et al. (1998) Estimation of impurity profiles of drugs and related materials, part 19: Theme with variations. Identification of impurities in 3-oxosteroids. *Journal of Pharmaceutical and Biomedical Analysis* 18: 511–525, with permission.

material. This is one of the reasons why drug authorities require the identification/structure elucidation of impurities and degradation products if their individual quantity exceeds 0.1% (impurity profiling). In possession of the structure the impurity can be synthesized and used (in addition to toxicological studies) as an impurity standard for the development of a selective method for its quantification. This is usually based on determining the HPLC/UV response factor relative to the drug material.

Figure 2 shows a general scheme of drug impurity profiling. As seen, this complex procedure is based on the combined use of a variety of spectroscopic techniques (UV, IR, MS, NMR) and separation methods, mainly HPLC and thin-layer chromatography (TLC), and to a somewhat lesser extent gas chromatography (GC), but the importance of other separation methods such as supercritical fluid chromatography (SFC), capillary

electrophoresis (CE), capillary electrochromatography (CEC), and so on is also increasing. Although, as mentioned earlier, the capability of UV spectroscopy as a structure elucidation tool is low as compared to MS and NMR, in favorable cases useful information can be obtained from the UV spectra generated at the very beginning of the studies making use of the rapid-scanning photodiode-array (PDA) spectrometers widely applied as detectors in HPLC instruments and the spectrum scanning facilities of TLC densitometers. This is why UV spectroscopy appears on the top of the scheme. An example is shown in **Figure 3**. The characteristic spectrum of nestorone with its chromophoric α,β -unsaturated 3-oxo group is curve 1. The extension of the conjugation in the case of 4,6-diene-3-one (curve 5) and 4-ene-3,6-dione (curve 4) type impurities leads to highly characteristic bathochromic wavelength shifts. Even the minor changes due to the introduction of

Figure 2 A general scheme for the profiling of related organic impurities in drugs involving the use of various spectroscopic and chromatographic techniques.

the auxochromic hydroxy groups at positions 6α and β (curves 2 and 3) are of diagnostic value or at least furnish important preliminary information to complement those obtainable by MS and NMR. The same applies to the UV spectra of the impurities in prednisolone in **Figure 1**.

The online and off-line application of MS and NMR in impurity profiling is discussed (together with other applications) in the following section.

NMR and MS in Drug R&D and Quality Control

Brief Overview of the Current Roles of NMR and MS in Drug R&D/QC

Our main aim here is to focus on the most traditional and most common use of NMR and MS in the pharmaceutical industry, that is, the structure elucidation of small organic molecules (other spectroscopic methods,

Figure 3 Diode-array UV spectra of nestorone and its related impurities. 1, Nestorone; 2, 6 α -hydroxy derivative; 3, 6 β -hydroxy derivative; 4, 6-oxo derivative; and 5, 6-ene derivative. For the source see **Figure 1**.

most importantly IR, can also have a significant role in a structure determination problem, but these are not discussed here). However, in order for one to properly appreciate the current trends and future possibilities of NMR and MS in that regard, it is required to first place structure-elucidation applications within the broader context of what other roles NMR and MS can play in the pharmaceutical industry. Without attempting to be comprehensive, the following brief overview tries to give an impression of the manifold NMR and MS applications that encompass the various aspects of drug research and development as well as quality control (R&D/QC).

Biomolecules

Biomacromolecules (typically polypeptides/proteins) represent a growing percentage of the new drug substances put to market worldwide. As a result, many pharmaceutical companies that have up until recently been interested mostly in small-molecule drug substances have started to integrate biotechnological research and production into their portfolio. Both NMR and MS play a critical role in providing the required analytical support for such projects. (HPLC)MS provides essential information on the purity of the sample and is typically the number one choice for verifying a peptide sequence in both the R&D and the quality control phases of production. NMR offers a methodologically independent and unique tool not only to confirm the amino acid sequence but also to gain insight into the liquid-phase secondary, tertiary, and quaternary structures of the molecule. However, circular dichroism is the method of choice in characterizing and comparing biomacromolecular high-order structure, with ancillary techniques such as IR and Raman spectroscopies providing valuable additional insights.

Metabolomics

Metabolomics aims to identify and quantify all small-molecule metabolites (the so-called metabolome) present in a biological system. This approach is gaining increasing interest in drug discovery, disease diagnostics, and treatment. From a drug R&D/QC point of view, the analysis of the global metabolic responses to drugs or diseases is of particular interest, since this allows, for example, the identification of biomarkers associated with certain desired or undesired effects and side effects. Monitoring such biomarkers during and after selecting a lead molecule (i.e., a 'leading' compound that exhibits a suitable pharmacological activity and whose chemical structure can be used as a starting point for structural modifications aimed at improving potency, selectivity, or pharmacokinetic parameters) can prove to be extremely useful while developing a drug. Currently, LC(GC, CE)-MS or the off-line ^1H NMR analysis of various biofluids, followed by suitable statistical pattern recognition, are the most important tools in that respect. Quite interestingly, the same NMR, MS, and statistical tools that have been developed for metabolomic studies can be applied directly to describe the impurity profile of a given drug substance or drug product at far lower concentration levels than would normally be of interest from a quality control point of view. However, such very low-level 'impurity fingerprints' are specific to a given line of production, and can be used efficiently to identify drugs originating from unethical sources or in patent infringement cases.

Drug design

Over about the past decade, NMR and MS have significantly transcended their 'classical' role as major structure elucidating tools for small organic molecules,

and have increasingly been applied in new and innovative ways to aid the drug discovery process. A growing number of approaches exist that utilize the special capabilities of these techniques. For example, NMR and MS can both report on the presence or absence of drug–receptor binding. In addition, NMR is uniquely suited not only to locate the drug–receptor binding sites of a protein, but is also capable of providing detailed information on the liquid-state 3D geometry of the receptor, as well as that of the drug, in the bound state. An in-depth understanding of this binding geometry for a specific target and drug can be well utilized for further lead design. An important variant of this strategy is SAR (structure–activity relationship) by NMR, which is a method allowing one to identify small building block molecules that bind to a target. These pieces are then combined into a single molecule so as to form a new lead with a better binding. However, investigations of this kind may often prove rather demanding in terms of instrument time as well as human resources, which is why such research is often outsourced by the pharmaceutical industry. A more practical approach that is usually better suited for in-house NMR investigations does not aim to obtain such detailed geometrical knowledge, but utilizes one or more of the many NMR methodologies that have been developed simply to screen for drug–receptor binding hits by investigating suitable lead-like molecule libraries. Such screening, often conducted in a high-throughput fashion, may be used either to find lead candidates or to validate hits found in biological screening assays. The latest application that is rapidly gaining widespread interest in the pharmaceutical industry is the use of NMR for fragment-based lead discovery, a concept resting on the thesis that drug-like molecules can be regarded as the combination of two or more individual binding epitopes (fragments). Screening for these binding epitopes using a selected pool of low-molecular-mass molecules is the essence of fragment-based drug discovery (FBDD). The binding affinities of fragments being relatively low, biophysical screening methods such as NMR are well suited for that purpose. Continuing advancements in NMR offer more detailed structural understanding of the drug–protein binding, which can prove invaluable in evaluating fragment hits and developing them into leads. A typical limitation of all these methods is that, as a rule, NMR can most conveniently be applied for the aforementioned investigations in the liquid state, which requires the use of soluble proteins as targets. However, the latest methodological developments in NMR, such as saturation transfer double difference (STDD) even allow the efficient screening of fragments binding to membrane proteins, which is a significant advancement considering the pharmaceutical industry's interest in such targets.

Structure elucidation of potential drugs and minor components in various matrices

Generally speaking, the structure elucidation of small organic molecules still represents the greatest demand placed on NMR and MS in the pharmaceutical industry. It is interesting to note that this 'traditional' role of NMR and MS seems to receive decreasing attention in the literature in light of their above-mentioned modern functionalities, often resulting in the impression that structure elucidation is a 'routine' procedure as compared to the more recent applications of NMR and MS in biomolecular research and drug discovery. Nevertheless, in a pharmaceutical R&D/QC environment small-molecule structure determination can often be an exacting task in terms of the involved technical, intellectual, and work-flow-management challenges, as well as the highly demanding time pressures.

NMR and MS provide complementary data on a molecule's structure: MS gives the molecular weight, which can be a crucial piece of information when investigating an unknown structure; moreover, accurate mass measurements on high-resolution mass spectrometers offer the possibility to uniquely determine the molecule's elementary composition. Additionally, the fragmentation patterns observed in the mass spectrometer can, in favorable cases, significantly limit the number of possible constitutional isomers that are compliant with a given elementary composition. However, this is still peripheral structural information as compared to that obtainable from NMR, which offers hundreds, if not thousands, of different one-dimensional (1D) and two-dimensional (2D) measurement techniques that report on the various through-bond and through-space interactions between the NMR-active nuclei within a molecule, thus allowing an unambiguous determination of constitution, stereochemistry, and conformational characteristics. More sophisticated NMR measurements, however, tend to be less sensitive and more time-consuming than recording, say, a 1D ^1H NMR spectrum, and the quality of the data obtained and the required measurement times (sometimes several hours or even days) depend critically on the detection sensitivity of a particular instrument.

Although MS and NMR generally complement each other in terms of the structural information they provide, they are inherently mismatched in that NMR is far less sensitive than MS. This does not pose a serious limitation on using NMR for synthetic samples that are typically available in at least milligram quantities. However, although high-quality MS spectra can be recorded easily (but yield limited structural information) from samples available in the nanogram or microgram range, obtaining NMR data (especially with a view to conducting information-rich 2D techniques) from such samples can be problematic or even impossible. No wonder that huge

efforts have been, and are being placed, on the one hand, on increasing the capabilities of MS to maximize its structural information content. As a result, using a variety of novel ionization techniques and obtaining high-resolution exact mass data from the whole molecule as well as from its fragments is now becoming more and more routine. On the other hand, recent years have seen a surge in the development and worldwide implementation of a number of innovative methodologies that significantly increase the NMR signal-to-noise ratio. Such methods include the cooling of the radio frequency coil circuitry that detects the NMR signal in the NMR probe to approximately 25 K to decrease the level of electronic noise, or making the detection coil from high-temperature superconducting materials, or designing capillary NMR probes that require the analyte to be dissolved only in a few microliters of solvent.

The above-mentioned advancements, when considered in conjunction with the latest developments in separation technologies and hyphenated MS and NMR methodologies, create a considerable space of options for how these techniques may be employed to tackle various structure determination problems that emerge in different technical, organizational, and even managerial settings. Finding, amidst these parallel developments, and within a given working environment, the 'best' research protocol to be employed on a given set of instrumentation, or envisioning the most efficient *modus operandi* for the future, is by no means easy. All these technologies have different inherent scopes and limitations, and it is not rare to find that reports of highly successful applications are more or less specific to a given project and to a special pool of know-how. In that sense, the literature often provides exaggerated and biased opinions based on 'success stories,' which means that a fair operative assessment of a given instrumentation requires a reasonable level of hands-on experience within a given R&D/QC architecture. For example, cold NMR probes are robust systems that allow easy sample-handling in traditional NMR tubes, but are costly in terms of initial investment and maintenance. On the contrary, capillary probes require more tedious sample preparation, and currently employ homemade RF coils, which may be less suitable in a pharmaceutical environment. As an additional consideration, the greater the certainty with which an unknown structure is intended to be resolved, the more time-consuming and technically demanding the investigations tend to be, which often conflicts with the massive time pressures that are typical in a dynamic pharmaceutical working environment. The contradictory requirements of speed versus 'depth,' together with the need to weigh the ensuing risks and the associated responsibility, are often major issues in choosing the most efficient course of action for any given structure elucidation problem. For these reasons,

different spectroscopic laboratories situated in different institutions often entertain different structure elucidation strategies, or even philosophies, depending on locally established work-flow protocols, traditions, know-how elements, organizational characteristics, and the specifics of the available instrumentation. The following text illustrates and briefly discusses this diversity through a few selected examples of synthetic and natural products, impurities, degradation products, and metabolites.

Synthetic products

Among the above-mentioned types of problems, the structure elucidation of synthetic products may seem to represent the most easily handled situation, since most of the samples synthesized by traditional chemical methods are available in pure (or relatively pure) form and in adequate quantities for direct MS and NMR investigations. In such cases, utilizing ultrahigh-sensitivity NMR technology may be regarded as superfluous; especially in light of the fact that the general strive to enhance NMR sensitivity is almost always presented in the literature in the context of the fundamental need to analyze very limited quantities of molecules. In reality, high NMR sensitivities can provide massive advantages in terms of time frame for structure determination and the level of certainty even with synthetic samples. For example, as a rough figure of estimate, if recording a decent ^{13}C NMR spectrum from a sample available in a few milligrams on a 400 MHz instrument equipped with a traditional ^{13}C NMR probe takes, say, 9 h, then a spectrum of similar quality can be recorded on a 800 MHz instrument, equipped with a cold probe, in only a few minutes. Similar time gains are of course achieved for 2D and many other special 1D NMR experiments. Quite obviously, whether it is affordable to undertake a special NMR measurement so as to further confirm or disprove a structural conclusion under tightly scheduled measurement programs and expensive NMR instrument times will depend critically on whether that experiment takes several hours or just a few minutes. The implications of the latter case are illustrated in **Figure 4** for a very simple case, in which the ^1H NMR spectrum (500 MHz), obtained from a few milligrams of a synthetic product, can be easily misinterpreted. Since the instrument was equipped with a cold probe, several 2D experiments could be affordably recorded within an hour, revealing the correct structure.

Impurities

Our scheme of small-molecule impurity profiling (**Figure 2**) reflects the concept that the structure elucidation of an unknown impurity can basically be carried out along the lines of three main strategies: online LC-MS/NMR, off-line MS/NMR without separation, and off-line MS/NMR of the isolated impurity. Owing to the

Figure 4 ^1H NMR spectrum (500 MHz) of a synthetic product obtained in the denoted reaction. According to the spectrum the end-product is a mixture, with the expected compound **2** being the minor component (characteristic signals of **2** are marked with arrows). From MS, the major component's molecular weight corresponds to that of the starting material **1**, and since the ^1H NMR spectrum of the major component also appears to be consistent with **1**, it is easy to conclude from the ^1H NMR spectrum alone that the reaction has been incomplete. However, further NMR investigations using ^{13}C and 2D data revealed that the major component is in fact **3**, and this offered a key piece of insight into the chemistry involved.

much lesser demand for sample quantity of MS, the usual sequence for the use of these techniques is $\text{MS} \rightarrow \text{NMR}$. **Figure 2** also reflects our fundamental precept that the off-line MS/NMR investigation of an isolated impurity offers the safest and operationally most flexible scenario for obtaining the most detailed spectroscopic information from the impurity. Also, isolating the impurity by (semi)preparative HPLC, TLC, or solid-phase extraction (SPE) guarantees that the obtained MS and NMR data correspond to the same substance (often there are ambiguities in that regard in the online or the non-separated off-line approach), and allows the option to return the sample into the spectrometer for further experiments in an iterative process of measurement followed by spectrum interpretation. Note that it is because of these reasons that the flowchart does not contain an 'information considered sufficient?' decision stage following the MS/NMR investigation of an isolated impurity, since in the vast majority of such cases modern MS and NMR instrumentation coupled with adequate human research competency *must* yield either a definitive structure or a viable structural proposition. However,

isolating the impurity may not always be the most constructive, or even an executable, approach. For example, under heavy time pressures or with preparative resources being engaged in other projects, or if the impurity is perishable during the isolation process, an online MS/NMR analysis or a direct off-line MS/NMR investigation without separation may provide adequate results on a significantly shorter timescale.

Choice of protocol depends, among several factors, very much on the complexity of the specific molecular structural problem at hand and on the available instrument functionalities. It is also important to see that in the latter respect the technical landscape is changing rapidly with the constant increase in the sensitivity and other methodological developments of MS and NMR. For example, one should note that enhanced NMR sensitivity is beneficial in all three strategies. On the one hand, with the use of an ultrahigh-sensitivity NMR spectrometer, much less of the impurity needs to be isolated, which can be realized on far shorter timescales and by using much less of the drug substance, and this can favor the isolation approach. On the other hand, in a stop-flow LC-NMR

Figure 5 (a) In a steroid active pharmaceutical ingredient (API), whose partial structure is displayed, two unidentified impurities were observed at the 0.1% level. In the ^1H NMR spectrum (500 MHz) recorded from 50 mg of the API, the impurities are not visible under normal vertical magnification. (b) Characteristic ^1H NMR peaks due to the impurities become visible on magnifying the region within the dotted rectangle of (a). These peaks allowed the conjecture that the two impurities had structures as shown in the figure, but did not provide conclusive evidence in that regard. (c) A $2\text{D}^1\text{H}$ - ^{13}C HSQC spectrum recorded of the API in a 10 h experiment on a cold probe exhibits such high signal-to-noise ratio that structurally conclusive cross peaks due to the minor impurities become visible in the presence of the main components' cross peaks. For example, the inset shows a blowup of the region marked with a rectangle, exhibiting a cross peak due to the $\text{C}(4)\text{-H}_2$ moiety in impurity 1.

setting, higher NMR sensitivities allow more of the sophisticated 1D and 2D NMR experiments to be conducted in the time window before diffusion of the chromatographic peak starts to significantly impair data quality. Finally, with the increased spectral resolutions offered by higher magnetic fields and with the growing detection, it becomes increasingly productive to attempt the structure determination of one or two small components in the presence of the main product without

separation. **Figure 5** shows an example where urgent structure elucidation of two unknown impurities at the 0.1% level of the drug substance was needed, and in this particular case, the problem could be resolved overnight without using off-line cold-probe NMR technology.

At present, the off-line and the online use of MS and NMR probably play almost equally important roles. The online approach usually begins with HPLC-MS.

Figure 5 Continued.

The molecular mass is easily obtainable using soft ionization techniques. Using the well-established HPLC-MS(MS) technique this can be expanded by obtaining fragmentation data. In the case of sufficiently volatile and thermally stable drugs GC-MS is also an important method. The online coupling of the other separation methods, listed in the preceding text, with MS is also available but yet seldom used in drug impurity profiling. Although only a relatively limited number of publications are available, the most important development of the past decade in the field of using online techniques in drug impurity profiling has been undoubtedly the introduction of HPLC-NMR. The hyperhyphenated technique of HPLC-(UV)-NMR-MS is also available but used so far in a few cases only.

As shown in **Figure 2**, based on the integrated information obtained from its spectra and its chromatographic retention behavior, a proposition is made on the structure of the impurity, which is then synthesized. With the aid of the impurity standard thus obtained, selective methods can be developed for the determination of the impurity as described previously.

Degradation products, metabolites, and natural products

In many ways the structure elucidation of degradation products, metabolites, and natural products meets with similar challenges, and requires the use of almost the same strategies, as discussed earlier for synthetic products and impurities. Degradation products in particular require the same type of problem-handling as impurities. Metabolites often represent a somewhat different scenario in that typically many unknown metabolites are present in minute amounts in the investigated biological substances, and this favors the use of online MS/NMR techniques. At present, metabolite identification is most typically based on HPLC-MS. Because of the inherent limitations of MS in structure identification, the use of high-resolution MSⁿ techniques for such investigations can be critical to gain as much structural detail as possible. No doubt the role of online NMR will rapidly increase in these investigations in the near future. Although many reports exist in the literature on the HPLC-MS-based structure elucidation of natural products, these types of compounds often exhibit more complex stereochemical features than typical nonnatural drugs or drug impurities. For this reason, the

in-depth structure elucidation of many natural products is heavily dependent on using online NMR techniques, but most efficiently in the isolated off-line mode. The use of LC-MS-SPE to quickly isolate micrograms of a natural product or metabolite and to provide MS information on the isolated material, which is then subjected to thorough NMR investigations in a high-sensitivity instrument, seems to be a highly promising approach.

Solid-phase studies

The solid-phase status of drugs and drug formulations (crystalline–amorphous characteristics, presence of polymorphic modifications, solvates, etc.) greatly influences their bioavailability. In addition to thermal and X-ray techniques, spectroscopic methods (IR, NIR, Raman, and solid-phase NMR) play increasing role in the characterization and standardization of these characteristics.

Acknowledgments

The authors thank Dr. Zoltán Béni, Sándor Mahó, and Dr. Zsuzsanna Santa for providing the examples shown in Figures 4 and 5.

Spectroscopy for Process Analytical Technology (PAT)

Process analytical technology (PAT), as a term, was defined by the US Food and Drug Administration (FDA) in 2004 with the specific aim to support and accommodate innovation in industrial quality control. The tools that are used under the definition are categorized as follows:

- Multivariate statistical analysis, mathematical models, and design of experiments
- Process analyzers, including spectroscopic sensors
- Process control
- Continuous improvement and knowledge management

The term PAT is usually referred to for applications in the pharmaceutical industry, which quite recently embraced these techniques compared to, for example, chemical, petrochemical, and food industry, where the same tools have been used under the name process analytical chemistry (PAC). One advantage of using PAT tools and especially spectroscopy-based process analyzers is that factors that are influencing the final product quality or quality parameters themselves can be monitored. This enables control of these factors, leading to less variation in the final product quality. Other important advantages are cycle time reduction, process optimization, 100% process control, and replacement of laboratory testing. Traditional process monitoring tools are simple sensors such as temperature, pressure, flow, and pH measurements performed directly in the batch process or on a process stream. However, with technological advancements and manufacturing efficiency

programs, much more sophisticated tools are entering modern manufacturing industry.

Many of the modern process analyzers used for monitoring and control are spectroscopic analyzers. The most general reason for this is that spectroscopic sensors can be used to quantify analytes and physical parameters of the samples. The instruments are robust and can be employed in a harsh production environment, withstanding humid conditions, vibrations, dust, and temperature changes. The instruments can be interfaced with the processes using quartz windows, fiber-optic probes, and flow cells or even remotely placed apart from the process, for example, remote near-infrared analysis of material passing on conveyor belts. At least three factors have been the driving forces for this development. First, with the advent of modern computers and multivariate data analysis (chemometrics), it has become possible to analyze the huge amounts of high-quality data that modern spectrometers are able to provide. Second, quartz-based optical fibers and sampling devices have made sampling unproblematic and highly reproducible. Third, the strong demands from consumers and regulatory bodies for the industry to produce safe and high-quality products have forced the industry to continuously develop PAT.

It is the synergy between rapid multivariate spectroscopic sensors and the new data technology called chemometrics that has revolutionized industrial internal quality control (**Figure 1**), and what has been seen thus far is only the tip of the iceberg. In the future, spectroscopic sensors will become cheaper and process control an integral part of manufacturing, with the ability to handle simultaneous information from multiple monitoring points.

Food and pharmaceutical processes and products are complex multifactorial systems for which a complete characterization of product quality and process control requires an integrated use of chemical, physical, microbiological, mathematical, and risk analysis tools. Spectroscopic analyzers play an important role in such an integrated approach.

The objective of this article is to provide the reader with an overview of spectroscopic process analyzers, their potential, and key issues for their usage such as sampling and data analysis. Advantages and disadvantages of the different sensors will be discussed in relation to information content, sampling, robustness, maintenance, and so forth.

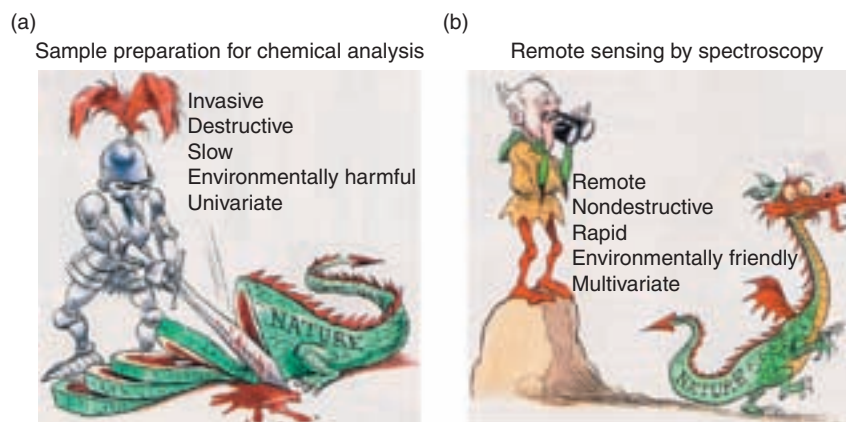

Figure 1 (a) Industrial quality control traditionally performed in the laboratory. (b) Advantages of spectroscopy and remote sensing.

Spectroscopic Process Analyzers

General Requirements for Spectroscopic Process Analyzers

The first thing to do when selecting a spectroscopic analyzer is to evaluate 'fit for purpose' criteria of available analyzers. A list with 'fit-for-purpose' criteria is shown in **Table 1**. The selectivity is important because most spectroscopic analyzers measure the analyte on a complex background of the sample matrix. The measured spectrum will contain contributions from many chemical and physical components in the sample, and the selectivity will depend on whether spectral features from the analyte may be separated from the spectral contribution from the other sample components. The accuracy of a spectroscopic method may not be very critical with respect to process monitoring if the difference between the measured and the true value is always the same (bias). The reason is that the objective of process control tools is typically to monitor 'changes' (contrasts) in a process attribute, not the absolute value. The precision of the analyzer, however, is a key criterion. Precision determines to which degree a change in the process can be accurately detected. Many spectroscopic analyzers inherently have high precision and are capable of analyzing the same sample numerous times showing very little difference. Range is another relevant criterion for the analyzer to be used for quantitative analysis. Obviously, the range must cover the region where the target analyte provides signals. Other aspects of the fit-for-purpose analysis are instrument robustness and long-term reliability. The analyzer is often placed in harsh environments and should be capable of sustaining vibrations, dust, humidity, and temperature changes. Another robustness criterion is method robustness, which deals with the ability of the analytical method to quantify the analyte with desired accuracy and precision when the sample matrix is changing due to

Table 1 Fit-for-purpose criteria when selecting a spectroscopic analyzer

Criteria	Explanation
Selectivity	The ability of a method to measure the analyte in the presence of other sample components in the sample matrix
Accuracy	The difference between the measured and the true value
Precision	The variability of repeated measurements of the same sample
Sensitivity	The detection limit and the quantification limit are evaluated in combination to identify the sensitivity of the analyzer
Range	The range of a method where the accuracy and precision are retained and the relationship between concentration and response is constant
Robustness	There are two types of robustness that should be considered: (1) analyzer robustness, which is important when using the analyzer in a manufacturing environment, and (2) method robustness toward external factors such as changing temperature, pH, and sample matrix effects
Speed	The amount of time it takes to obtain an analysis result
Ease of operation	The practical handling of the analyzer
Integration with IT systems	Instrument should be able to attach to and communicate with existing manufacturing IT systems to handle data exchange and analyzer operation

changes such as pH, temperature, or sample matrix composition changes.

The *need for speed* of the spectroscopic method and concomitant data analysis should match the process dynamics, allowing regulation of the process before the process is finalized. This means that the instrument should be able to interface with the process either via an in-line probe or by extracting samples continuously from

Figure 2 The concepts of off-line, at-line, on-line, and in-line process monitoring by spectroscopy.

a process side stream and analyzing them in, for instance, a flow cell. Alternatively, the instrument can be placed at-line adjacent to the process, in case the process dynamics allows some time delay from the sample removal until the control is initiated. It is also very important that the analyzer is easy to operate because the daily maintenance and usage are often left to process operators and not chemists. Finally, it is becoming increasingly important that the new process analyzer can be integrated with existing manufacturing IT systems.

Generally, four different levels or modes of implementing a spectroscopic sensor in an industrial production environment are defined (**Figure 2**). The lowest level is the off-line situation where the sample is taken from the process stream and brought to the central laboratory for spectroscopic analysis. This is still the most common sampling situation because it offers considerable flexibility and because the often expensive and very sensitive instruments can be placed in clinical dust-free environments and be operated by chemists and trained laboratory personnel. The next level is the implementation of the sensor at-line near the process line, yet still with manual sampling. When compared to the off-line sampling, at-line sampling offers faster response for process control, but with the disadvantage that the instrument must be more robust and dedicated. The real advantages of PAT are first realized when the sampling is performed on-line or in-line. In the in-line situation, the spectroscopic probe is inserted directly into the process stream or the process stream is monitored remotely by, for example, a spectroscopic camera. In the on-line situation, the process line is automatically sampled or may be diverted to a side stream directly passing into the analyzer and thus facilitating real-time process control or even rapid process dynamics.

Considering the process dynamics is of paramount importance when implementing PAT. **Figure 3** shows a very illustrative example of the difference between

off-line sampling in the laboratory and on-line sampling implemented for dosing of ammonia during an amidation process. In the figure, values predicted from a spectroscopic analyzer (solid line) are superimposed on the previous manual ammonia titrations (red dots). Quite obviously, the titrations done once an hour (red dots) do not describe the full process dynamics (solid line), and the new spectroscopic analyzer provides a complete new insight into the process dynamics.

Spectroscopic Techniques

PAT is of little value without high-quality data. Spectroscopic sensors are able to furnish process engineers with such data. When a spectroscopic method is introduced in an industry, the key question “What would be the appropriate choice of our new spectroscopic process analyzer?” arises. The answer will depend not only on the quality parameter to be measured but also on the possible sample presentation, the need for nondestructiveness, robustness, and, last but not least, possible spin-off in terms of other relevant quality parameters to be measured. This article will briefly mention a few relevant spectroscopic sensors for PAT and discuss the advantages and disadvantages (**Table 2**). These spectroscopic methods are based on different regions of the electromagnetic spectrum and on different physical principles, and have naturally different sensing capabilities. But they share the ability to provide rapid multivariate information on the sample being monitored, which in turn makes it possible to simultaneously determine several quality parameters.

Visual spectroscopy coincides with the human senses and is therefore a most important quality parameter for evaluating nearly all products. Implementing visual analyzers in manufacturing industries is therefore rather common from simple LAB (lightness and a and b color-opponent dimensions in color model) color

Figure 3 On-line near-infrared quantification of ammonium versus off-line manual sampling and traditional chemical analysis in remote laboratory. Within 2 days, the set point for the ammonia concentration changed due to processing conditions.

measurements of meat to advanced multichannel grading of furs.

Trace substance sensitivity can be obtained by fluorescence sensors, as most substances do not fluoresce, and emission spectra can therefore be measured against a black background. Important fluorophores include proteins (containing the amino acids tryptophan, tyrosine, and phenylalanine), coenzymes, vitamins, caffeine, chlorophyll, polyphenols, flavanoids, and aflatoxins. Robust fluorescence sensors based on fiber optics already exist, but their on-line implementation has not yet been exploited. Fluorescence sensors have great potential for monitoring fermentation reactors, and fingerprinting with fluorescence spectroscopy is a powerful technique, which is highly complementary to vibrational fingerprinting. However, for the industry to realize the potential for such indirect methods based on trace amount of indicator substances, a new paradigm shift may be required.

One of the most fascinating spectroscopic methods is the omnipresent near-infrared spectroscopy, which over the past decade has been successfully implemented as a fast at-line/on-line/in-line quality control in almost all facets of food and pharmaceutical manufacturing. It was early recognized that the almost holographic vibrational overtone and combination bands residing in the near-infrared spectral region (**Figure 4**) contain an abundance of chemical information comparable to the mid-infrared region. This region of the electromagnetic spectrum contains overtones and combination tones of the fundamental vibrations normally found in the mid-infrared

region. As these signals are repeated throughout the region, the near-infrared spectrum can be regarded as a holographic signature of the mid-infrared spectrum. Near infrared happens to reside in a region of the electromagnetic spectrum where the wavelengths of the light coincide with particle size and particulates in many samples and thus give rise to strong scatter phenomena. **Figure 5** shows how three samples of exactly the same compound differ tremendously depending on the particle size of the sample being measured: amorphous sucrose, fine crystalline sucrose, and coarse crystalline sucrose. This information can be utilized in crystallization processes and drying processes. Near-infrared sensors have the additional advantage that the instrumentation is relatively simple and that the radiation may be transmitted through quartz, making the use of optical fibers feasible. One instrument and an optical switch can thus monitor several measuring points hundreds of meters apart. In the food industry, near-infrared spectroscopy is implemented to monitor traditional quality parameters such as moisture, protein, and fat content as well as product-specific attributes. The trend in on-line near-infrared application goes in the direction of fingerprinting raw materials, end products, and an optimal reaction end-stage utilizing the full holographic potential of near-infrared spectroscopy.

Like sensors built on near-infrared technology, mid-infrared sensors have substantial potential as a quantitative quality control tool for the food industry, but thus far, it has mainly found use in off-line liquid analyses of

Table 2 Overview of commonly used spectroscopic techniques for process monitoring

<i>Spectroscopy</i>	<i>Molecular phenomena</i>	<i>Characteristics</i>
Fluorescence	Electron transitions	Emission technique Few molecules fluoresce Quartz is transparent Water is inactive Sensitive down to parts per billion Broad signals Selective (two wavelength parameters)
Visual	Valence electron transitions	Absorption technique Few molecules absorb Quartz is transparent Water is transparent Sensitive down to parts per million Broad signals Valuable quality index as replacement for human senses
Near infrared	Overtone of molecular vibrations	Absorption technique Nearly all molecules absorb Quartz is transparent Water absorbs strongly Sensitive down to 0.01% Broad signals Holographic information on biological samples containing anharmonic X–H bonds
Infrared	Molecular vibrations	Absorption technique Nearly all molecules absorb Quartz is strongly absorbing Water absorbs strongly Sensitive down to 0.01% Sharper signals Carbonyl stretch is strong and selective
Raman	Molecular vibrations normally found in the mid-infrared range but by using near-infrared and visual radiation	Scatter technique Nearly all molecules scatter Quartz is transparent Water has medium absorption Sensitive down to 0.1% Sharper signals C=C is strong; N ₂ is visible; inorganics Fluorescence may be prohibitive Sample heating may be prohibitive
¹ H nuclear magnetic resonance	Nuclear spins and chemical shielding	Resonance technique All molecules with protons Not an optical technique Water has strong but localized absorption Sensitive down to parts per million Sharp signals Requires an external magnet; can handle opaque samples; provides a volume measure; requires stopped flow; has very high resolution

especially milk, edible oils, and wine. The main obstacle to implementation of mid-infrared sensors for industrial quality control is the inability to use optical fibers.

Raman spectroscopy, based on weak, inelastic scattered side bands arising, when illuminating a sample with a strong monochromatic laser light, appears to be an attractive alternative to the practically impossible on-line implementation of mid-infrared sensors. Like mid-infrared spectroscopy, Raman scatter measures the

fundamental molecular vibrations, and like near-infrared radiation, Raman scattering can be transmitted in optical quartz fibers. To date, a small number of customized on-line Raman applications have been developed in the manufacturing industries, and their high sensitivity to C=C, C≡C, and C≡N bonds, low sensitivity to water, and high selectivity to inorganic substances (salts) and polymorphs can be of potential interest for niche applications.

Figure 4 The electromagnetic spectrum showing the position (λ , E) of near infrared.

Figure 5 Visual and near-infrared spectrum of three samples of sucrose: amorphous sucrose, fine crystalline sucrose, and coarse crystalline sucrose.

The vibrational spectroscopies – near-infrared, mid-infrared, and Raman – have in common that practically all substances will give rise to substantial absorption/scattering effects, for which information on trace substances or detailed conformational information is normally hidden in spectra of complex samples such as food. Moreover, they have in common that they are absolutely nondestructive, as they contain energies from approximately 40 kcal mol^{-1} to approximately 1 kcal mol^{-1} , not enough to break covalent bonds ($50\text{--}130 \text{ kcal mol}^{-1}$) and, for example, to initiate autoxidation (Figure 4).

The potential advantages of implementing spectroscopic sensors for quality control directly in food and pharmaceutical processes will create a continuous quest for still more informative and multivariate sensors to be developed. High-resolution nuclear magnetic resonance (NMR) is probably the most successful and versatile spectroscopic technique yet to be developed. Although its

implementation as an on-line monitoring tool is severely hampered by the requirement of a strong homogeneous magnetic field, it is foreseen that this technique will also invade the more advanced segments of the food and medical industries for quality control. Among many other reasons, NMR is such a versatile technique, which absolutely noninvasively can monitor samples from process streams as volume measurements with extreme resolution and very detailed molecular information.

Image-Based Spectroscopy for Process Monitoring and Control

In recent years, technologies that combine spectroscopy and microscopy have entered the stage of process analyzers. With these technologies, it is possible to map a process sample and visualize the spatial distribution of constituents in heterogeneous samples. An image is made

up of adjacent pixels. Each pixel represents an area on the surface of the imaged sample. In image spectroscopy, a spectrum is recorded in each pixel; that is, the spectrum is a representation of the chemical composition on a specific area on the sample surface. By analyzing all pixel spectra, a chemical image is created of the entire sample surface and the spatial distribution of the different sample matrix components displayed. It has to be emphasized that, in general, the spatial resolution of the spectroscopic techniques mentioned earlier is mainly limited by the physical diffraction limits and thus by the wavelength used. Visible and near-infrared microscopy is thus limited to a spatial resolution of approximately $1\text{ }\mu\text{m}^2$, whereas infrared imaging is limited to approximately $10 \times 10\text{ }\mu\text{m}$ – in all cases, far from the resolution required to measure, for example, subcell structures.

For some processes, the spatial information is more important compared to bulk properties. For example, the total analyte concentration in a tablet sample is difficult to relate to the dissolution behavior of the tablet, whereas near-infrared imaging analysis of the particle sizes of the analyte agglomerates within the tablet is often related to the dissolution of the analyte.

Image technologies traditionally use the visible spectral region for ordinary processes, but vibrational spectroscopy-based imaging, that is, ATR (attenuated total reflectance) probe mid-infrared imaging and near-infrared reflectance imaging as well as Raman imaging systems and fluorescence imaging, are now found in development laboratories in many pharmaceutical companies. These systems are most suited for smaller samples, for example a tablet surface, and difficult to interface with a process stream in a manufacturing area. For larger samples such as a process surface, camera-based systems with array detectors are being used. With these systems, the spatial distribution of powder components in a powder blender can be assessed, and by using this information, the mixing process can be terminated when the blend uniformity is best. With near-infrared imaging cameras, spots of fecal contamination on poultry in an industrial cleaning process can also be visualized and the process repeated for those objects that are insufficiently cleansed. Other examples are fluorescence imaging of fish bones in automated filleting processes, final grading of mink furs by combined near-infrared and visual imaging, and foreign body detection in raw material sorting of waste material plants.

The major obstacles for image process technology are the large amounts of data that are created by each image and practical things such as sample illumination difficulties. It is anticipated that more spectroscopic methods in the future will be image-based systems as computer power is increased, detectors and instruments are improved, and the algorithms to analyze the image data are further developed.

Data Analysis

Just collecting more and more numbers does not in itself lead to improved production, better control, or more profit. Most spectroscopic analyzers provide thousands of data points in each spectrum. When the instrument is attached to a process and automatically records spectra with a high frequency, the resulting data material will consist of hundreds of thousands data points that need to be analyzed to create valuable information that can be used for process monitoring and control. To turn information into operational knowledge, multivariate latent-variable models need to be used.

Extracting the relevant information from complex sensor signals requires substantial work and expertise. Modeling the data includes handling, for example, seasonal variations in the raw material, harsh cleaning and production conditions, instrumental instability, and instrument-to-instrument differences. Little guidance is offered to industrial end users and manufacturers on how to deal with such problems. Even for the most well-established near-infrared spectroscopy applications, there are few official guidelines. In the scientific literature, only general solutions are given, and these are usually not of practical use in real production. The challenge and workload of robust calibration remains an effective stopper for widespread use of spectroscopic devices.

An explanation of the wealth of chemometric methods for preprocessing, calibrating, variable selection, exploring, designing, transferring, and maintaining multivariate models is unfortunately outside the scope of this article. However, the basis for unsupervised and supervised exploration of large data sets, namely, the bilinear chemometric methods such as principal component analysis (PCA) and partial least squares (PLS), has amply demonstrated their superior performance when analyzing spectroscopic information in quality control sensors. The advantage of such methods is that when analyzing first order multivariate data (samples $\times$ spectral variables), they can facilitate process trajectory exploration, outlier detection, interference compensation, and noise reduction, resulting in more efficient and robust calibration models and very often new insight into the process.

Sampling

When the ‘fit-for-purpose’ are criteria are finalized, there are some practical considerations to take into account. One of the most important and critical considerations is sampling. Different sampling elements are described in Table 3.

To decide on the two elements *sampling position* and *interface*, a good starting point is to use quality risk management, for example, Ishikawa diagrams and hazard analysis and critical control point (HACCP) analysis, to

Table 3 Sampling elements

<i>Sampling</i>	<i>Explanation</i>
Sampling position	The positioning of a probe is extremely important. The sampling position should be in a position that is representative of the parameter that needs to be characterized. Also, there are practical considerations such as sample density variation or temperature variation that could affect the method robustness.
Sampling for reference analysis	Many spectroscopic analyzers are calibrated against a reference method. This means that during analysis, samples are removed from the process for reference analysis and later correlated to the spectra with chemometrics. It is important that the reference samples are removed from the process close to the sampling position to achieve a high accuracy of the spectroscopic method.
Interface	It should be investigated what type of interface is optimal for a given method. Depending on engineering obstacles and process dynamics, an at-line solution is sometimes sufficient, but for automatic process, controls that provide on-line and in-line interfacing are usually required. Other considerations are risk of process contaminations in sterile production environments and operator hazards with toxic products. In cases where the analyte can only be quantified with an extremely sensitive technique, for example, NMR, it is difficult to interface the analyzer with the process. In such cases, a solution could be to install a pneumatic tube system (also called Lamson tubes) that connects the process facility with the remote off-line laboratory. The process operator can then remove a sample from the process and send the sample ultrafast to the laboratory for analysis.
Sampling frequency	The sampling frequency is linked to the process dynamics that needs to be monitored and controlled. These considerations should also include the control dynamics, that is, speed of data analysis plus time for regulation to take place.
Method acquisition setup	Many spectroscopic instruments have numerous acquisition parameters to adjust. For example, the acquisition time can be adjusted to average out unwanted effects in the spectra such as influence from air bubbles and particulates. Also the spectral resolution and the scan speed of interferometer-based instruments must be adjusted to provide the optimal sensitivity.
Removal of disturbing factors	As the analyzers are placed in harsh production environments, disturbing factors should be identified and their negative influence on method robustness removed. For example, if a process that has taken place at very low temperatures is monitored, there is a risk that water vapor in the production room can condense inside fiber-optic probes and distort the measured spectrum. This disturbing factor can be removed by flushing the probe with a dry inert gas, such as nitrogen, during analysis.
Fouling	As many spectroscopic methods are measuring the process via fiber-optic probes or sapphire windows, there is a risk of fouling that should be prevented. One solution could be to use automatic retractable probes that can enter and exit the process and undergo cleaning procedures between measurements. Other solutions are cleaning of windows and probe tips by compressed air pulses between measurements or heating of probe tips.

get an overview of the process. Based on the output from an Ishikawa exercise, experimental work is done using design of experiments principles, and available and appropriate process analyzers can be fitted to the process. The spectroscopic data can be evaluated with chemometrics to reveal process dynamics and identify which analyzer provides most insight into the process, that is, which analyzer is best correlated to product quality.

Process Monitoring and Control

Manufacturing methods can largely be divided into continuous or batch-operated manufacturing. In continuous manufacturing, the objective of a spectroscopic analyzer would typically be to monitor the level of certain analytes, provide information to a feed-backward

control, and keep the level of the analytes within specified ranges. Accurate, precise, and speedy analysis by spectroscopy combined with a feed-backward control provides a well-controlled process that is easily adjusted to different levels and with low variability. In the following example (**Figure 6**), ammonium was determined by on-line near-infrared spectroscopy and used for automatically controlled addition of ammonium to maintain certain desired levels that gave a very precise and swift control with much narrower specification of the ammonium concentration and thus the product.

In batch-operated manufacturing, the manufacturing process recipe is driven with different serially connected unit operations. As an example, **Figure 7** depicts a batch-operated manufacturing process where the raw materials enter process A, followed by process B, before the final product is available.

Figure 6 Automated control by on-line near-infrared feedback. The arrow indicates the point at which a spectroscopic analyzer was introduced for control of the process. The step change at day 12 indicates a change in recipe.

Figure 7 A batch-operated manufacturing is typically made of several unit operations providing the final product. Spectroscopic analyzers can be placed throughout the chain of unit operations either by at-line-based methods, for example, analyzing complex raw materials, or by on-line or in-line based methods, monitoring the progression of individual unit operations.

There are several opportunities for process monitoring and control of batch processes. Spectroscopic analyzers can be used to monitor the progression of each step and provide feed-backward control to achieve optimal product quality under that particular unit operation and determine the finalization of the step before proceeding to the next unit operation. In industries that use complex and variable raw materials, spectroscopic analyzers can be used to analyze the raw materials entering the manufacturing facility and decide how to process them optimally. By fingerprinting the complex raw materials and using a feed-forward control loop, the manufacturing process is adjusted to accommodate raw material variations. The same control principle can be applied by spectroscopic analysis of the intermediary product leaving process A and then used to feed-forward control process B for optimal recipe settings.

A typical example of raw material analysis is near-infrared analysis of yeast extract, a typical amino acid source used in fermentation. Several batches of yeast extract were analyzed with near-infrared spectra. The different yeast extract batches were then used in fermentations, and the foaming tendency in the batches

was recorded. Foaming is a nondesirable situation in the fermentation process. In **Figure 8(a)**, near-infrared spectra of yeast extract samples from different batches are depicted. The spectra were analyzed with a PCA model (**Figure 8(b)**), and in the score plot, the scores are colored according to foaming tendency of the different yeast extracts. The clustering in the scores was well correlated with the foaming tendency, which shows how the PCA model of the near-infrared spectra could be used to predict the foaming tendency, and with this control, manufacturing problems could be avoided.

With rapid in-line spectroscopic analyzers, it is possible to reveal process variations and control these. In-line near-infrared spectroscopy was used to quantify the water concentration in a pharmaceutical powder mixture during a granulation and drying process in a fluid bed reactor (**Figure 9**). The first part of the process was a two-step spray phase where first an aqueous polymeric solution and later pure water were sprayed onto the powder that was fluidized by heated air blown from the bottom up through the fluid bed reactor. A short spraying pause when shifting to pure water caused a minor drying of the powder (horizontal arrow in **Figure 9**), which was

Figure 8 Scatter-corrected near-infrared spectra of yeast extract raw material (a) and PCA score plot (b). The spectra and scores are colored according to foaming problems in fermentation (black circles = no foaming, red triangles = little foaming, green stars = heavy foaming).

Figure 9 Loss on drying (w/w%) is analyzed directly in a fluidized bed using a near-infrared reflectance probe. Three lots were produced with identical process settings, but the near-infrared analyzer revealed large differences due to variable input air conditions. Shift from polymeric solution to pure water is identified with a horizontal arrow.

clearly detected by the near-infrared reflectance probe. After the spray phase started the drying phase, which was automatically terminated when the powder reached a set-point temperature. Three lots were produced with identical process recipes, all dried to the same final product temperature. The lots showed large variations in the water content during the spray and drying phases as well as final water concentration. A large difference in drying time was observed (from 38 min of Lot C to 58 min of Lot B). Prolonged drying time can cause final quality defects such as increased mechanical shear on powder granules, resulting in too many fine particles. The differences in water concentration and drying kinetics are caused by typical noncontrollable process

variations such as airflow variations and humidity differences in the inlet air to the fluid bed reactor. By using near-infrared reflectance, water concentration can be monitored and controlled. For example, the inlet air temperature can be adjusted continuously in a feedback control loop and the drying terminated by endpoint control. This will decrease product variability and reduce likelihood of quality defects.

Challenges by Implementation of PAT

PAT represents a silent revolution in industrial quality control by introducing real-time process monitoring

through fingerprinting of complex process streams using spectroscopic sensors and thereby moving from inferential monitoring and control towards 100% process control of core quality parameters. There are many opportunities for process monitoring and control by using spectroscopic analyzers. As many manufacturing processes are made of several unit operations in series, single-point monitoring is naturally extended to plant-wide monitoring using multiple monitoring points. A plant-wide monitoring and control scheme will raise new challenges such as data management and compilation and analysis of strings of data that characterize the complete manufacturing process. Plant-wide monitoring by a single process analyzer is possible with near-infrared analyzers with multiplexing capability where numerous fiber-optic connected probes can be attached.

Another challenge will be to analyze all available process data simultaneously. As chemometric methods are capable of simultaneously analyzing plentiful data origins from different sources (e.g., spectroscopy, temperature, and pressure), it will be natural to use them in a holistic data analysis strategy and monitor the manufacturing process by all available data. This means that data integration, data timing, and alignment will be key issues in future process control.

Continuous learning through data collection and analysis over the life cycle of a product is important

(PAT guidance, 2004)

Introduction

Biological molecules as therapeutic agents have proved to be an important and growing sector in the pharmaceutical industry since the approval of the first human recombinant protein, insulin, in 1982. Advances in recombinant DNA technology over the past 25–30 years have led to an increase in the types of biotechnology products (biopharmaceuticals) seeking regulatory approval, such as vaccines, peptide and protein therapeutics, DNA, and gene therapy products.

Spectroscopic techniques have an important place in the suite of analytical methods that can be used to characterize these large, complex molecules where the biological activity depends on the primary, secondary, tertiary, and quaternary structure. For most biotechnology products, there is a regulatory requirement that the biological activity or 'potency' of individual batches is tested upon the release of a batch. To determine its activity, the product is assessed by not only physicochemical techniques but also a biological assay that reflects the mechanism of action in the body. However, in a few cases, there may be adequate data to link the physicochemical attributes to functional activity. Recombinant insulin and growth hormone products are well characterized by physicochemical methods; therefore, it is unnecessary to test each batch by bioassay (although some regional differences in regulatory requirements exist). With advances in analytical instrumentation to study the structural components of biopharmaceuticals, this approach may also provide insights into the development of similar products. Spectroscopic techniques are also used to demonstrate batch-to-batch consistency and

to demonstrate that the products' higher-order structure is stable over the stated shelf life. In addition to characterization of purified product, spectroscopic methods can be applied to monitor 'upstream' bioprocessing steps (fermentations) or subsequent purification stages. These are attractive technologies as they allow noninvasive, nondestructive monitoring during production that can help in identifying failures earlier than at end product testing.

This article does not provide detailed theory of each spectroscopic technique that may be used in the study of biological molecules; this is covered elsewhere in this publication. Rather, it reviews the most commonly used techniques in the biopharmaceutical research and development process. The analytical techniques that are appropriate for these wide-ranging scenarios will also be dependent on the phase of the drug development process, which is also reviewed here.

Regulatory Drivers

Characterization of a biopharmaceutical starts early in the development process, where structural conformations or drug–ligand interactions may aid drug discovery and candidate selection. Early characterization benefits product development by providing supporting data to demonstrate the comparability of material used throughout development. As the production process is optimized or scaled up, small changes in the process may affect the structure of the product.

A set of guidelines exists for the procedures that are appropriate for the development and registration of biopharmaceuticals, set out by the International Conference on Harmonisation of Technical Requirements for Registration of Pharmaceuticals for Human Use (ICH). ICH makes recommendations on ways to achieve greater harmonization between the regulatory regions in the interpretation and application of technical guidelines and requirements for product registration. Guideline Q6B specifically covers "Test Procedures and Acceptance Criteria for Biotechnological/Biological Products," including the physicochemical properties that should be studied. Within this section, some spectroscopic techniques are specified:

Spectroscopic Profiles

The ultraviolet and visible absorption spectra are determined as appropriate. The higher-order structure

of the product is examined using procedures such as circular dichroism, nuclear magnetic resonance (NMR), or other suitable techniques, as appropriate.

What does this mean in practical terms? Which other techniques are appropriate? To understand this, it is necessary to think of the various stages of product development, as some techniques may be more suitable than others at different stages. Spectroscopic techniques may be used to provide supporting structural information about the molecule itself, which is required to confirm the identity of a biopharmaceutical for batch release, prove the consistency or stability of a batch compared to a stated reference material, or provide a more 'global' analysis of the production process or formulation conditions.

In addition to the requirements for product development and final product testing, in 2004 the United States Food and Drug Administration set out the principles for process analytical technology (PAT), for designing, analyzing, and controlling the manufacture of pharmaceuticals. This initiative is more advanced for the manufacture of chemical pharmaceuticals; however, the biopharmaceutical industry has started integrating chemical, physical, and mathematical analyses directly into processes, and spectroscopic analyses have also been extensively investigated for this purpose. Raw data from in-line sensors (spectra, chromatograms, or physical sensor data) can be used to control production by processing multivariate data sets with chemometric methods such as principal component analysis. A recent FDA document states: "The new quality-by-design approach will focus on critical quality attributes related to chemistry, formulation, and process design."

Determination of Biopharmaceutical Structure

The types of biological molecules approved for therapeutic use or in development can be broadly classified into protein or nucleic acid-based pharmaceuticals. The primary structure of a protein is the amino acid sequence that makes up the polypeptide chains, which are subject to chemical and biological post-translational modifications. The folding of these chains into α -helices, β -sheets, and random coils defines their secondary structure. Nucleic acid-based biopharmaceuticals are polymers of nucleotides linked by phosphodiester bonds that form single- or double-stranded helices. These can further fold to form the tertiary structure. Protein or DNA three-dimensional structure can be studied in detail by techniques such as X-ray crystallography; however, routine application of this technique to biopharmaceutical manufacture is impractical, as the molecule must be studied in its crystalline form and that

involves a lengthy and sample-dependent preparative step. Techniques that are of interest to analysts in the biopharmaceutical industry tend to be less time-consuming (or can be automated, therefore requiring less user time) and more economical in terms of sample consumption and equipment purchase (Figure 1).

Ultraviolet Visible (UV-Vis) Spectroscopy

Determination of product characteristics or concentration using UV-Vis spectroscopy is important for any step in the biopharmaceutical development process, from the research laboratory to in-process analysis. The complete UV-Vis spectrum can provide lots of information about a molecule; scanning through the UV wavelengths (190–400 nm) into the visible region (400–700 nm), the spectra can be used to determine the absorption maximum at a particular wavelength or give a broad featured profile of a particular sample. The absorption of tyrosine (Tyr), tryptophan (Trp), and cysteine (Cys) enables determination of protein concentration by measuring the absorbance maximum at 280 nm. If the amino acid sequence of the protein is known, the absorption coefficient of the protein can be calculated theoretically or determined empirically by amino acid analysis. The absorption maximum at 260 nm allows calculation of the concentration of nucleic acid in the sample, while the ratio between the readings at 260 and 280 nm provides an estimate of its purity. Absorption at higher wavelengths (330 nm or higher) is usually caused by light scattering and indicates the presence of particulate matter; values greater than 0.3–0.4 at 350 nm are taken as a quantitative measure of protein aggregation and are often used during downstream development (along with visual inspection) as a quick determination of the suitability of purification or handling steps.

For the batch release of biopharmaceuticals, UV-Vis is used as a routine measurement of protein or DNA concentration that must fall within the specification for amount of product per vial. Visual inspection (appearance test) will also assess the optical turbidity, although turbidity measurements using visible light at 600 nm are also used for determining biomass and other characteristics during fermentation (see the section 'Optical turbidity').

Circular Dichroism (CD)

The primary structures of protein or nucleic acid-based biopharmaceuticals comprise chiral molecules that absorb circularly polarized light or fold into chiral conformations. CD occurs when proteins or nucleic acids absorb left- and right-hand circularly polarized light slightly differently; the difference at each wavelength is small but gives rise to spectra typical for different types of secondary structure, for example in proteins α -helix,

Figure 1 Summary of spectroscopic techniques currently used in biopharmaceutical product development.

β -sheet, and β -turn. Far-UV spectra (180–260 nm) are due to absorption by peptide bonds whereas the signal observed in the near-UV region (240–360 nm) is principally due to the aromatic side chains of Trp, Tyr, and Phe and disulfide bridges in the absence of other chromophoric groups. Sensitivity to structural changes makes CD very useful for comparative purposes, particularly for batch-to-batch analysis or in accelerated stability trials where the molecule is exposed to extremes of temperature or pH in order to identify degradation pathways that the molecule may undergo. The major advantages of CD are it is fast (minutes compared to hours), it is non-destructive, and it uses relatively inexpensive equipment. Calculation of secondary structural content can be conducted using a number of algorithms based on spectra of well-characterized proteins of known secondary structure, although objective pattern recognition techniques such as principal component analysis are increasingly utilized to identify significant structural changes.

Fourier Transform Infrared Spectroscopy (FT-IR)

FT-IR (typically performed in the mid-IR range) examines the wavelengths of infrared radiation that are

absorbed by the sample. Each compound has a characteristic set of absorption bands; for proteins these include the amide I and amide II bands (~ 1650 and 1550 cm^{-1} , respectively) from the peptide bonds that link the amino acids. FT-IR is particularly good for the measurement of β -sheet structures and can analyze samples in aqueous solution (albeit with difficulty), in nonaqueous solution, or in the dry powder state. Bands in the 1100 and 1000 cm^{-1} region reflect vibrational frequencies of carbohydrates or nucleic acid bonds.

FT-IR is heavily used during biopharmaceutical formulation activities to examine changes in native secondary structure upon addition of different buffering systems or excipients, or lyophilization of the molecule. Lyophilization is often used to increase the shelf life of biopharmaceuticals; however, development of aqueous formulations is attractive due to reduced manufacturing costs and ease of handling. A major limitation of FT-IR in the analysis of aqueous formulations is the absorption of water, which overlaps with the amide I band of a protein; however, this absorption band can be mathematically subtracted and technologies such as attenuated total reflectance (FT-IR ATR), which increases signal-to-noise ratios by reducing the effective pathlength for measurement, are being used. Currently the technique is used

largely as a qualitative tool for biopharmaceutical analysis but is moving toward quantitative analysis for structural components of proteins. Instrumentation is relatively economic to buy, and software for spectral analysis and deconvolution is well developed. Again, principal component analysis or pattern recognition techniques have proved useful for detecting changes in protein secondary structure.

Fluorescence Spectroscopy

Proteins display intrinsic fluorescence due to the presence of aromatic amino acids such as Trp, Tyr, and Phe. For example, after excitation of Trp residues at 295 nm, light is absorbed and re-emitted at a longer wavelength. The chemical environment of the fluorophores determines their fluorescence properties, caused by the energy transitions that give rise to particular wavelength shifts. The technique can therefore be a useful comparative tool for purified proteins undergoing formulation development or accelerated stability studies. When the micro-environment of the aromatic residues changes, residues can be exposed to aqueous solvents instead of a hydrophobic region of the protein, resulting in a shift in the emission spectrum. The spectral features are very broad, however, and this limits applicability for batch release of biopharmaceuticals. As a tool for in-process monitoring, the technique has utility because many intracellular components show fluorescence properties. Recently developed fluorimeters use several excitation and emission wavelengths to monitor components of fermentations such as NAD(P)H and to provide information about the energetic state of the cell and oxygen supply and the metabolism of cells in industrial processes.

Raman Spectroscopy

There are a number of applications of Raman spectroscopy to protein analysis, as it can provide structural details on secondary structure (peptide backbone conformation), aromatic residue side chains, disulphide bridges, and their local environments. It can also be used for analysis of polynucleotides with bands attributable to purine or pyrimidine ring structures and phosphate groups.

Raman spectroscopy monitors the scattered radiation from a molecule; a small portion of this scattered radiation has frequencies different from that of the incident beam, as energy exchanges occur between the incident photons and the molecule. Raman scattering is, however, a very weak physical phenomenon and has traditionally been limited to analyzing proteins at high concentrations (20–50 mg ml⁻¹), often in a research laboratory. With the development of more sensitive spectrometers the sample requirements have reduced to concentrations as low as 1 mg ml⁻¹. A major advantage of Raman spectroscopy

compared to infrared spectroscopy is that water does not give strong signals in the region of interest; therefore, the technique can be used on aqueous solutions. Proteins can exhibit background fluorescence that can mask the Raman scattering, but advanced techniques such as surface-enhanced Raman spectroscopy (SERS) have been developed to overcome this. Raman spectroscopy can be applied to *in situ* product quality analysis, product contaminant identification, product characterization, and raw material analysis, and it has the potential to be applied as a tool for process analysis for monitoring analytes in-line during the upstream or downstream process stages.

An allied technique is Raman optical activity (ROA), designed for the measurement of chiral molecules. This technique measures the intensity of Raman scattered right- and left-circularly polarized light. A particular area of interest for biopharmaceutical development is glycoprotein ROA that can simultaneously provide information on secondary and tertiary structures of polypeptides and information about the carbohydrate components.

Near-Infrared Spectroscopy (NIR)

NIR absorption spectroscopy, ranging from 12 820 to 4000 cm⁻¹, is increasingly used for monitoring fermentation processes to measure the concentration of biologically important bonds (aliphatic C–H, aromatic or alkene C–H, amine N–H and O–H) that absorb in the NIR range. Each chemical structure contributes to a characteristic position, shape, and size of the analyte's absorption bands. Process-related changes can be captured in the NIR spectra of complex culture media, to simultaneously monitor concentrations of nutrients, metabolites, product formation, or biomass. Combination of NIR spectra with chemometrics methods is being used to determine critical parameters in processing that are important for product quality.

Dielectric Spectroscopy

Dielectric spectroscopy is used as an in-process analytical technique that measures the electrical properties of cells in a fermenter, by exposing them to a radio frequency electrical field. Cell type, size, and concentration determines the capacitance measured, with the added benefit that only viable cells with intact membranes act as capacitors, allowing discrimination between cell debris or air bubbles, which can affect optical turbidity measurements.

Optical Turbidity

Optical density or turbidity measurements (most popularly at 600 nm) are widely used to estimate biomass in microbial and mammalian cell processes. The light

scattered by a culture sample will depend on the concentration of cells, the species, and the strain of microbe, and the growth-calibration must be performed for each type of cell line. Measurement of cell density is an important parameter to monitor during a fermentation process, preferably using a sterilizable probe inserted directly into the fermenter; however, measurements can also be made off-line in a spectrophotometer. Optical density methods will detect all particulates (including nonviable cells and debris) present in a sample.

Nuclear Magnetic Resonance (NMR)

NMR spectroscopy analyses the chemical structure of proteins, oligosaccharides, and nucleic acids. It provides atomic level details of the molecules in solid or solution state, can study flexibility and dynamics of biological samples, is nondestructive, and can be used to analyze the conformational integrity of a sample. Historically, the technique has been limited to proteins of less than 40 kDa and in milligram quantities; it requires expensive equipment, specialist operators, and data analysis. Finding solution conditions that allow proteins to be stable and soluble at high concentrations to perform 3D experiments is essential. However, different modes of NMR are suitable for one-off characterization, and more recently have been investigated as screening techniques for raw materials and for final product quality analysis.

Method Validation

Validation of an analytical procedure is carried out in order to demonstrate that it is suitable for its intended purpose. When choosing spectroscopic techniques that are amenable to validation, it is necessary to determine whether a change in structure or content may be reliably and robustly detected at a range of concentrations and in the sample matrix in which it will be analyzed. Consideration should also be given to the context in which it may be used such as in-process analysis, stability testing, or final product quality testing.

Taking the example of an assay for final product release based on determination of content by UV, adoption in a quality control lab requires that the following criteria are met:

- Quantitative analysis should be performed.
- Sources of variability should be understood to set specifications or report the result that the sample 'conforms to reference.'
- Where necessary, assay should be validated according to ICH guidelines.
- Assay should be simple to run and able to process large sample numbers.
- Minimal data interpretation should be required.

Repeatability	—	+
Intermediate precision	—	+
Specificity	+	+
Detection limit	—	—
Quantitation limit	—	—
Linearity	—	+
Range	—	+

Note: Adapted from publicly available ICH Guidelines for identity and content testing of pharmaceuticals.

The ICH guidelines advise on those assay characteristics that should be considered when validating an assay, which are summarized in **Table 1**. Spectroscopic techniques are most likely to be validated to confirm the identity of a sample, for example, by comparing a spectrum to that of a reference standard. They may also quantitate the active component in a drug substance or drug product, or some other selected component within it. Recently, there has been an urgent need to confirm the identity of adulterated heparin products causing deaths and serious adverse events in patients using these drugs in the United States. Revised pharmacopeial monographs for heparin sodium and heparin calcium have been prepared to include proton-NMR spectroscopy and there is significant interest in the development of optical techniques for the same purpose.

Understanding the appropriate level of analytical method development during the product development life cycle is an important factor in the choice of techniques used in biopharmaceutical production. In preclinical and early stage clinical development (Phase I), methods may be employed that may not need full validation, sometimes described as 'qualified' or 'validated for Phase I' methods. The methods must still be based on good measurement principles that have demonstrated the necessary sensitivity, accuracy, and precision, in order that the assay is fit for purpose. Full method validation requires gathering of information on the assay performance over an extended period of time. The data undergo statistical analysis, and the variability of the results is documented. This can be a multioperator, multisite study that is expensive and time-consuming, and therefore generally occurs later in development when there is more confidence that a product will make it to market.

With advances in analytical instrumentation, the sensitivity, throughput, and data interpretation of spectroscopic methods will continue to improve and to be applied to biotechnology and biopharmaceutical analysis. The regulatory framework is open to 'suitable techniques, as appropriate' to complement those techniques

that are already well established, with the ultimate goal of proving the integrity, safety, and efficacy of biological molecules that are administered to patients.

Spectroscopy of Ions

John P Maier, University of Basel, Switzerland

This article is reproduced from the previous edition, volume 3, pp 2182–2189, © 1999, Elsevier Ltd.

Ions and radicals are transient species which are not readily accessible to conventional techniques for spectroscopic characterization. There are essentially three problems to be overcome—the production in sufficient concentration, the availability of a sensitive technique enabling their IR or electronic spectra to be recorded and the ability to identify the observed spectral features. The involvement of mass-selection not only leads to the solution of the last problem, but enables methods based on particle detection—fragment ions, electrons and photons—to be incorporated. The aim of the spectroscopic studies is, on the one hand, to provide a fingerprint of the species by its vibrational or electronic spectrum, enabling its identification in various terrestrial and space environments, and on the other hand, the spectroscopic analysis leads to information on geometric structures, force fields and fundamental interactions.

Ions are known to be important entities in space, for example in comets and interstellar clouds and their electromagnetic spectrum is the means not only to identify them but also to gain physicochemical data on their surroundings. The same applies in the noninvasive monitoring in the laboratory, such as of plasmas and flames. It is the purpose of this article to give some examples of the studies on mass-selected species, both of their electronic and IR spectra. This was originally achieved in the 1990s in experiments measuring the electronic absorption spectra of mass-selected cations, anions and neutral radicals in an inert neon matrix at ≈ 5 K and more recently in the gas phase for anions following electron photo-detachment. IR spectroscopy of ionic complexes, prototypes of fundamental interactions in chemical and biochemical phenomena, and intermediates of ion–molecule reactions can also be achieved with a mass-selected technique involving vibrational predissociation spectroscopy in an ion trap.

Absorption Spectroscopy in Neon Matrices

Technique

This method combines mass spectrometry and matrix isolation. The study of transients trapped in the neutral environment of a rare gas is an established spectroscopic approach. It suffers, however, from selectivity; though

sufficient concentrations of elusive radicals and ions can be obtained in rare gas matrices, spectral overlap as a result of the simultaneous presence of many such species usually restricts the interpretation. This is overcome by growing matrices with mass-selected ion beams.

Figure 1 shows the essential features of the instrument developed. A number of ion sources have been used, hot-cathode discharge for anions and cations as well as a cesium sputter one for anions. These have been designed to generate copious amounts of specific ions. The extracted ions are passed through an electrostatic deflector into a quadrupole mass spectrometer before codeposition with excess neon to form a matrix at ≈ 5 K. Several stages of differential pumping are incorporated in the instrument to isolate the ion source from the cryo-surface. Mass-selected ion currents in the nA range are usually required for a successful measurement and the kinetic energies of the ions are chosen to be in the 50–150 eV range. The deposition takes about 2 h resulting in a thin neon matrix (≈ 150 μm) over about 1 cm^2 area. A typical ion density is 10^{15} to 10^{16} cm^{-3} . The neutrality in the matrix is assured by the presence of counter-ions generated *in situ* either from impurities present or via the species deposited themselves.

The absorption spectrum of the mass-selected molecules is measured by a technique which enables the whole length of the thin matrix to be interrogated. The species and neon are condensed on a copper substrate and the light is passed through slits into the side of the matrix and traverses it parallel to the metal surface. By this means, absorption path lengths of 1–2 cm are

Figure 1 Apparatus used for the measurement of absorption spectra of mass-selected cations, anions and neutral radicals in neon matrices.

achieved. For measurements in the IR, only a reflection configuration can be used, leading to two orders of magnitude lower sensitivity.

A major aim of this technique is to identify and locate the characteristic electronic transition of carbon chain-like species. This is for two reasons: (1) to be able to consider their relevance in astrophysical phenomena in view of their spectral features and (2) to plan gas-phase experiments with this knowledge.

Electronic Spectra of Cations

As an example, the polyacetylene cations HC_nH^+ are considered. They are readily produced in a hot-cathode discharge source fed with a mixture of acetylene diluted with helium. Ion-molecule reactions lead to polymerization. When a particular species is selected according to the number of carbon atoms in the chain, with currents in the nA range, and codeposited with excess neon, the electronic absorption spectra can be measured. **Figure 2** shows the characteristic strong transitions for the species with an even number of carbon atoms. The polyacetylene cations have an open-shell electron configuration with $X^2\Pi$ ground states and the band systems apparent correspond to $\pi^*-\pi$ electron excitation, i.e. to electronic transitions of $^2\Pi-X^2\Pi$ symmetry.

In the spectra observed, the first band at lower energy is the most intense and the origin transition. The peaks

lying to shorter wavelength involve the excitation of vibrational modes in the upper electronic state. Under the conditions of the experiment, rotational motion is eliminated because the species are held rigid in the surrounding neon lattice. The low ambient temperature of 5 K constrains the population to the vibration $v = 0$ level in the ground electronic state from which all transitions then originate. In addition, the geometry change on π -electron excitation is relatively small; hence the origin bands dominate and this leads to the relative simplicity of the spectra (**Figure 2**). The vibrational pattern and the types of normal modes excited indicate that these are transitions of linear (or quasilinear) polyacetylene chains.

The electronic transition shifts towards the IR by regular increments (≈ 100 nm) for each acetylene unit. This is a characteristic feature of carbon chain molecules and can be simply modelled by an electron in a box treatment. In addition to the inverse energy dependence on the length of the chain, the oscillator strength of these transitions grows. This is a contributing factor for the successful detection of the longer species in the laboratory even though the attainable ion current of the mass-selected species is decreasing. It is also one of the attractive features for consideration of such species in astrophysical phenomena. Finally, with the location of the transition in a neon matrix, the corresponding measurements in the gas phase have become a realistic

Figure 2 Electronic absorption spectra of mass-selected polyacetylene cations in 5 K neon matrices.

proposition. Typical shifts for the electronic transitions of the cations (Figure 2) should be in the $100\text{--}200\text{ cm}^{-1}$ range to the blue on passing from the neon matrix to the gas phase.

Electronic Spectra of Anions

In an analogous way to the measurement of the electronic absorption spectra of cations, those of anions can be obtained. A sputter source has been used to generate the pure carbon anions. In this, a graphite rod is bombarded with cesium ions. The carbon species are formed by sputtering and gas phase processes and the ions produced are extracted for mass-selection. Sufficient ion concentrations have been attained for the spectroscopic studies of carbon anions in the C_4^- to C_{20}^- range. The carbon species are unusual among anions in that they have large electron detachment energies (3–5 eV) and possess one or more bound excited electronic states. This is illustrated in Figure 3 by the observed electronic spectra of the C_{2n+1}^- anions detected after mass-selected deposition.

Up to four band systems are discernible (for $n = 4, 5$) and these are the various ${}^2\Pi\text{--}X\text{ }{}^2\Pi$ transitions arising by $\pi\text{--}\pi$ electron excitation. The arrow placed on the wavelength scale (Figure 3) indicates the electron detachment threshold in the gas phase. Thus, the highest lying excited electronic state is stabilized with respect to the isolated state as a result of solvation by the neon atoms.

The vibrational structure is again relatively simple, indicating a chain structure for the carbon skeleton. In addition to the frequencies of the fundamentals, which can be inferred from the electronic spectra – these are mainly the totally symmetric stretching modes and some bending ones excited in double quanta – antisymmetric, IR active modes have also been observed with this approach. This followed the recording of the infrared spectrum after the mass-selected deposition by a reflection arrangement.

Electronic Spectra of Mass-Selected Neutral Radicals

The technique has been extended to the spectroscopic study of mass-selected neutral species. In the case of the carbon molecules this is best accomplished by selection of the corresponding anions and subsequent detachment of the electron either during or after growth of the matrix using a broad band photon source. By this means the long sought electronic spectra of the linear carbon chains C_{2n+1} ($n = 2\text{--}7$) could be identified. Some of these are shown in Figure 4. The electronic transition corresponds to $\pi^*\text{--}\pi$ excitation. The carbon chains with odd numbers of atoms are closed-shell species and the symmetry of the observed band systems is ${}^1\Sigma_u^+ \text{--} X\text{ }{}^1\Sigma_g^+$. In contrast, the chains with even numbers of carbon atoms are paramagnetic with a $X\text{ }{}^3\Sigma_g^-$ ground state. Their transitions have been detected for C_{2n} ($n = 2\text{--}5$) by this method. The band systems of the

Figure 3 Absorption spectra of mass-selected carbon anions in neon matrices at 5 K showing several ${}^2\Pi\text{--}X\text{ }{}^2\Pi$ electronic transitions.

Figure 4 Electronic absorption spectra ($1\Sigma_u^- \leftarrow X1\Sigma_g^+$) of neutral carbon chains observed after mass-selected codeposition of their anions with neon at 5 K and detachment of the electrons by photon illumination.

linear forms of the larger species are not apparent in the spectra, providing direct experimental evidence for a change of geometrical structure above C_{10} . In contrast, the linear chains C_{2n+1} persist beyond $n=8$. Thus, the potential of the technique of combining mass and matrix-isolation spectroscopies for the characterization of neutral species in addition to the ionic ones is clear.

Electronic Spectra of Anions in the Gas Phase

The electronic spectra of carbon chain anions have now also been measured in the gas phase incorporating a mass-spectrometric technique. Because the energy region of the electronic transition is known from the measurements on the mass-selected species in neon matrices (see above), the gas-phase study is made that much easier. The sensitive approach adopted involves selection of the respective anion, laser excitation and photodetachment. A schematic outline of the apparatus is given in **Figure 5**.

The anions are conveniently prepared in a pulsed d.c. discharge source containing a few per cent of acetylene in argon expanded in a supersonic free jet with a backing pressure of about 9 bar. The argon carrier gas ensures clustering and cooling of the formed anions. The beam is passed through a skimmer into a time-of-flight mass spectrometer. The ion of interest, e.g. C_7^- , is

Figure 5 Experimental arrangement used to observe the electronic transitions of mass-selected carbon anions in the gas phase.

identified by its flight time after which the excitation and photodetachment takes place. In the case of C_7^- , the $A\ ^2\Pi - X\ ^2\Pi$ transition (cf. **Figure 3**) is sought. A tunable laser is scanned in this wavelength region while a second laser photon of fixed energy (532 nm) causes the photodetachment whenever the first photon is in resonance with the electronic transition. The total energy of the two photons absorbed exceeds the electron affinity of C_7 . The detection is usually of the neutral mass-selected species (C_7).

In **Figure 6** is seen the recorded spectrum of the $A\ ^2\Pi - X\ ^2\Pi$ transition of C_7^- . The striking feature is the narrow line width of the bands, attributed primarily due to the production of cold anions (20–40 K) in the supersonic discharge source. The analysis of the vibrational structure is straightforward—it is consistent with a transition of a molecule linear in both the ground and excited electronic state. The excitation of the three totally symmetric stretching modes in progressions and as combinations in the upper electronic state is apparent. The absence of bands corresponding to bending modes is associated with a relatively rigid structure of C_7^- . Similar measurements in the gas phase have now been realized for carbon anions in the C_5^- to C_{11}^- range. Such data then allow a direct comparison with astronomical observations, for example, on the diffuse interstellar bands, a long-standing puzzle.

Figure 7 The setup of the instrument used to measure infrared spectra of ionic complexes via vibrational predissociation spectroscopy.

Infrared Spectra of Ionic Complexes

Approach

The aim is to measure IR spectra in the gas phase of ionic complexes. As illustration, the H_2-HCO^+ species is considered. Such ionic complexes are intermediates in ion-molecule reactions and have been detected by mass spectrometry in the earth's stratosphere. The forces involved in their binding are ion(induced) dipole, and are involved in biological phenomena. The binding energies are generally intermediate between those of van der Waals species and those involving hydrogen bonds. In the case of H_2-HCO^+ , the binding energy is $\approx 1400\text{ cm}^{-1}$, whereas it is merely 150 cm^{-1} for $He-HCO^+$, another of the species studied.

There are three concepts in the experiment, the schematic outline of which is given in **Figure 7**. The first is the production and selection of the complexes. This can be achieved only at low temperatures and

consequently a supersonic expansion combined with electron impact ionization has been used. To produce H_2-HCO^+ , a 15:1 mixture of H_2/CO at a total pressure of 4–5 bar is passed through a pulsed orifice and the complex is formed in the expansion reaction where 70 eV electron impact produces the ions. The latter are extracted via a skimmer into a quadrupole mass spectrometer and the chosen ion is injected into an octopole, and confined for the desired time. The second part involves the excitation of a vibrational transition of the ionic complex. Radiation from a tunable infrared laser passes down the middle of the octopole and intercepts the species. The photon energy is chosen so that it exceeds the binding energy of the ionic complex. When the infrared transition is excited, in due course the complex dissociates. Because the vibrational predissociation is slow for such ionic complexes – the transfer of energy from the mode excited is inefficient, e.g. $\nu_1(H-H)$ in H_2-HCO^+ , into the fragmentation

channel ($\text{HCO}^+ + \text{H}_2$) – there is usually no spectral broadening.

The fact that fragment ions are produced leads to the third underlying principle of the experiment, namely the sensitive detection of the absorption process by counting the resulting fragment ions. Thus, in the octopole both the ionic complex ($\text{H}_2\text{-HCO}^+$) and the product ion (HCO^+) are constrained, but the final quadrupole (**Figure 7**) is tuned to transmit only the fragment ion. The IR spectrum of an ionic complex is observed by monitoring the intensity of the fragment ions as a function of the laser frequency.

Vibrational Spectrum of $\text{H}_2\text{-HCO}^+$

Figure 8 shows an IR spectrum for the complex in the 2500–4500 cm^{-1} region. The two strong bands are the ν_1

Figure 8 Infrared spectrum of the mass-selected $\text{H}_2\text{-HCO}^+$ ionic complex recorded with the apparatus shown in **Figure 7**.

(H–H stretch) and ν_2 (C–H stretch) fundamentals as well as combination bands involving the bending levels (in the spectrum only the $\nu_2 + \nu_4$ band is indicated others lie adjacent to the ν_2 peak). Both ν_1 and ν_2 frequencies are lower than the values for the isolated units indicating a weakening of the H–H and H–C bonds in the ionic complex. Thus it can be seen that this approach enables vibrational spectra of mass-selected ionic complexes to be recorded, like the spectra of stable molecules, although the concentrations of the ionic species are minute in comparison.

When the resolution is increased (0.02 cm^{-1}), rotational structure on some of the bands becomes apparent. This is particularly striking for the ν_1 band (4060 cm^{-1}) of the H–H stretching motion (**Figure 9**). The rotational structure, with $\Sigma\text{-}\Sigma$ and $\Pi\text{-}\Pi$ components, is consistent with a T-shaped semirigid symmetric top. Assuming that the HCO^+ unit has similar bond distances as in the free species, then the rotational constant evaluated from the analysis of the rotational structure implies a H_2 to HCO^+ distance of $\approx 175\text{ pm}$.

Similar studies have now been accomplished on a number of ionic complexes ranging from R-HCO^+ , $\text{R-N}_2\text{H}^+$ to species such as R-NH_4^+ , with $\text{R} = \text{He, Ne, Ar}$ and H_2 . This leads to an insight and understanding of the interactions occurring between neutral species and ions as well as of their geometrical structure.

Solvation of Ionic Cores

As the measurement of the IR spectra is based on mass-selected species, the number of ligands surrounding the ionic core can readily be varied. This is illustrated in **Figure 10** for the case of the HCO^+ surrounded by an

Figure 9 Rotationally resolved ν_1 band (H–H stretch) of the $\text{H}_2\text{-HCO}^+$ ionic complex.

Figure 10 Infrared predissociation spectra of the HCO^+ ionic core solvated by specific number of argon atoms.

increasing number of argon atoms where the changes of the ν_1 transition energy are followed. The IR spectrum can be recorded for each mass-selected entity by monitoring the dominant photofragmentation product ion. The characteristic shifts and patterns in the IR spectrum lead to models of solvation and representation of structural changes.

The addition of the first argon atom results in a shift of 274 cm^{-1} in the ν_1 frequency (H–C stretch) relative to that in the free HCO^+ ion. This large change indicates that the argon atom is bound at the hydrogen end. The analysis of the rotational structure points to a linear, rigid

geometry. The argon atom is located about 213 pm from the ion core. As further argon atoms are added, the ν_1 frequency shifts in the opposite direction, towards higher energy, in a fairly systematic fashion; by the time 12 argon atoms are solvating the ionic core, the red shift relative to the free HCO^+ fundamental is back to 156 cm^{-1} . As can be seen from **Figure 10**, the incremental shifts are largest for 2–5 argon atoms, then there occurs a small red shift, while in the range 6–12 atoms the blue shift is rather small. When 13 argon atoms are attached, the ν_1 band splits into two components.

These spectroscopic signatures can be rationalized in terms of a simple structural model. The first argon atom occupies a linear proton-bound position. The next 2–5 atoms form the first primary solvation ring at one end. The addition of 5–11 argon atoms forms the second ring at the other end. The marked splitting with 13 atoms, as well as a distinct drop in the binding energy, is associated with the beginning of a second solvation shell and the presence of at least two isomers.

The EPR/Spin Label Technique

Spin labelling is used to monitor physical, biophysical or biochemical properties of substances, proteins, lipids, and cell membranes. This is achieved by introducing a persistent free radical (such as a nitroxide) into the system, which is sensitive to this physical surrounding. Such spin probes are ideally suited to investigate the dynamic aspects of molecular interactions. A spin probe study should proceed in two steps. The first is an analysis of the EPR spectra, yielding physical parameters about the orientation and the motion of the spin probe in the host system. The second step is the interpretation of these parameters in terms of relevant molecular models for the formulation. The section on spin labels will use as an illustrative example the results obtained when various perfluorinated polyether (PEPE) materials containing reactive anti-vesicant agents were labelled with stearic acid spin probes. These spin-labelled ointment formulations were exposed to different concentrations of vesicant (blistering) agents. The attachment of the spin label at a particular site on an ointment formulation provides a unique means of probing the physical environment in the formulation. If the probe molecule is placed at or near the reactive component of the formulation, then the magnetic resonance experiments may be used to determine the penetration profile. However, there have been many examples of spin labelling in other fields, including liquid crystals and cell membranes.

EPR/Spin Label Technique for Antivesicant Agents

Initial screening was performed using the electron paramagnetic resonance (EPR)/spin-label technique by inserting stable organic nitroxide free radicals, known as spin labels, into a heterogeneous complex system consisting of

polytetrafluoroethylene (PTFE) particles and fluorinated oils of the proposed formulation. The EPR spectra of the spin labels are very sensitive to the rate at which the label is able to reorient after a magnetic field (B_0) is applied. Thus, knowledge of this functional dependence allows the evaluation of the degree of mobility and permeability permitted in the environment of the label. Ointment formulations of reactive topical skin protectants (rTSPs) or topical skin protectants (TSPs) based on PFPE (i.e. fomblin[®]) were prepared and spin labelled. Four N-oxyl-4,4'-dimethyloxazolidine derivatives of stearic acid, 5-NS, 7-NS, 12-NS and 16-NS, were used as spin probes. The spin-labelled vehicle, fomblin[®] and the vehicle containing chloroamide [chlorinated glycoluril; 1,3,4,6-tetrachloro-7,8-diphenyl-2,5-diiminoglycoluril (S-330), an antivesicant] were exposed to various concentrations of 2-chloroethyl ethyl sulfide (half-sulfur mustard). The physical insight into the molecular motion is defined by the order parameter (S) which depends on the frequency and amplitude. The EPR experiments detect only the motion and orientation of the $-N^{\bullet}-O$ group, so the order parameter is related to the x, y, z coordinates. Therefore, S depends on the depth of penetration of the paramagnetic group into the vehicle (fomblin[®]) and on the chemical composition of the reactive antivesicant under investigation. The net change of the viscosity of the vehicle and the chemical composition were seen to affect the penetration profile.

The value of S obtained from the EPR data provides an analytical tool for comparison of the formulation of topical skin protectants and reactive topical skin protectants. The changes in the interior of this heterogeneous system of the labelled-TSP or labelled-rTSP (controls) were compared with exposed labelled-TSP/or rTSP. The spin-labelled formulations were exposed to the vesicant agents in a dose/time-dependent manner. The results show that the EPR/spin-labelling technique provides an analytical tool for determining the resistance of rTSP to the breakthrough and fluxes of vesicant agents.

The formulated candidates were labelled with stearic acid spin probes. Four kinds of N-oxyl-4,4'-dimethyloxazolidine derivatives of stearic acid (Figure 1) were used as spin probes. The nitroxide group ($-N^{\bullet}-O$) is attached at various positions along the fatty acid chain to situate the nitroxide groups at different depths in the hydrophobic interior of this heterogeneous complex system of TSP or rTSP. These probes are amphiphilic with polar regions

Stearic acid spin labels:

stearic acid derivative with N-doxyl group:

Figure 1 Chemical structure of the stearic acid spin labels.

which anchor the probes at the hydrophilic interface and the large, rigid steroid frameworks embedded in the lipid chain region. The largest hyperfine splitting (32 G) occurs when the magnetic field is parallel to the long axis of the fatty acid (and hence perpendicular to the plane of a well-ordered multilayer system). These steroid probes lack the rigidity of the group to which the doxyl moiety is attached. It is the behaviour of the lipid to which the $-N^{\bullet}-O$ group is attached that is important, so the order matrix is usually transformed to the molecular coordinate system, with z as the long axis of the spin label. It is in the molecular coordinate system that the S -matrix has axial symmetry. The outermost EPR lines move in and the line widths become narrower as the doxyl group moves from C-5 to the C-7, C-12 and C-16 positions.

The mixture of the formulation labelled with the spin probe was placed in a tissue cell sample holder (illustrated in **Figure 2**) for EPR measurement at room temperature. Once the EPR spectra of the control samples were recorded and characterized, titration experiments were performed on the same control with the particular vesicant agent under study. The vesicant agent, an oily liquid, was carefully distributed over the surface

Figure 2 EPR cavity cell for semisolid samples.

area using a plastic spatula. This dispersion process was performed without disturbing the surface of the labelled formulation. The EPR quartz flat cell was maintained at room temperature in a chemical fume hood for an hour to allow venting of the volatile agent and, after one hour, the EPR spectra were monitored as described for the control samples.

The EPR of the labelled-formulation control exhibits two low-field peaks as illustrated in **Figure 3**, which shows the EPR spectrum of a vehicle (fomblin[®]-RT-15) incubated with 5-doxyl stearic acid. The spectrum resembles that of an immobilized spin probe. The value of S of the strongly immobilized probe can be calculated from the spectra using the equation:

$$S = \frac{(T_{\parallel} - T_{\perp})}{3[(T_{zz} - a^1)/2]}$$

where $T_{\parallel}$ is the outer hyperfine splitting, $T_{\perp}$ is the inner hyperfine splitting, a^1 is $(T_{\parallel} + 2T_{\perp})/3$, and the tensor $T_{zz} = 32$ G. A change in S could be interpreted as representing a net change in the breakthrough and flux of the vesicant agent.

Some general principles should be followed in such formulation studies. (1) The use of experimentally determined 'low' probe-lipid ratios is a requirement. A sufficient quantity of the spin probe should be incorporated into the formulation to permit the recording of an EPR trace with a reasonable signal-to-noise level. (2) The spectral parameters $T_{\perp}$ ($A_{\perp}$), $T_{\parallel}$ ($A_{\parallel}$) and S derived from the EPR spectra should be plotted as a function of the vesicant concentration under study. If titration experiments indicate optimal conditions of probe-lipid ratios, then S may be used as a measure of formulation fluidity. (3) It must, however, be remembered that S is a function of

Figure 3 EPR spectrum of a formulation incubated with 5-doxyl stearic acid. The spectrum is typical of an immobilized spin-probe where $T_{\parallel}$ is the outer hyperfine splitting ($A_{\parallel}$) and $T_{\perp}$ is the inner hyperfine splitting ($A_{\perp}$).

both the motion of the probe and the polarity of the environment of the probe. (4) The probe spectral perturbation could be monitored by initially loading the formulation with probe and continuously measuring the EPR spectra to identify 'low' probe concentrations for formulation systems that destroy the EPR signal of the spin label with time. The decrease in probe concentration could be estimated from a double integration of the EPR trace. The decrease in the various spectral parameters could be plotted as a function of time.

The $-\text{N}^{\bullet}-\text{O}$ moiety is attached directly to the hydrocarbon, as illustrated in **Scheme 1**. The probe is incorporated into the lipid portion of the perfluorinated grease and produces an EPR spectrum of an immobilized spin-label probe. An idealized cross section of this heterogeneous system is illustrated in the schematic representation I. The fatty spin-label (A) intercalates with the long hydrophobic chain normal to the plane of the matrix. The rigid spirane structure of the doxyl group places the z -axis (arrow) of the nitroxide parallel to the extended lipid chain. Thus, the direction of maximum splitting will be observed when the magnetic field (B_0) is normal to the plane of the matrix (i.e. along the arrow A); the splitting becomes progressively smaller as the matrix is rotated in the magnetic field, and the minimum splitting occurs when the matrix is parallel to the magnetic field.

In principle, the polarity profile could be determined by measuring the three-hyperfine splitting constants T_{xx} , T_{yy} and T_{zz} for the $-\text{N}^{\bullet}-\text{O}$ group at various positions along the lipid chain. In practice, none of these parameters can be measured directly because of the partial motion average of the electron-nuclear dipolar interaction. An indirect method of obtaining the polarity profile is to estimate $T_{\perp}$ and $T_{\parallel}$ with the spin labels in randomly oriented samples. The $-\text{N}^{\bullet}-\text{O}$ group at the C-5 position in the lipid matrix has been reported to be in

Scheme 1 A fatty acid spin probe incorporated into a very complex heterogeneous system that consists of a particular probe (0.2–10 μm) and a lipid matrix. The axis of motional averaging Z' is the normal on the matrix surface. The arrow (i.e. along the arrow A) indicates the direction of the nitroxide z' -axis.

an environment that is more polar than the C-12 and C-16 positions which are in a more hydrocarbon-like environment (**Scheme 1**).

Humidity is a very important factor in such studies since vesicant agents hydrolyse at a relatively rapid rate. The polarity profile can be studied using lipid films supported on glass wool in a hydration chamber. These samples can be equilibrated at 100% relative humidity or dehydrated over phosphorus pentoxide (P_2O_5); the removal of water would effectively abolish the polarity profile. The main point is that the defined parameter S provides an operationally relative change at some depth in this complex heterogeneous system. Ion transport across lipid films can be studied by measuring the maximum and minimum splitting for the $(-\text{N}^{\bullet}-\text{O})$ group at various positions along the lipid chain. In addition, a penetration profile into the lipid matrices can be measured.

The order parameter S depends on the depth of penetration of the paramagnetic group $(-\text{N}^{\bullet}-\text{O})$ into the homogeneous hydrophobic vehicle, the viscosity of the fluorochemical material and the chemical properties of

the vesicant agent under investigation. Therefore, the net change in viscosity of the vehicle and the chemical composition affect the penetration profile. The probability that the paramagnetic group of the probes will be located at different depths in this complex heterogeneous system provides a unique tool to observe the permeation process at a molecular level. In addition, if we assume that the labelled and the unlabelled lipids (base oil of the formulation) intercalate to different depths in the lipid matrix, then to account for the large effect at the C-5 position, the vesicant agent must penetrate to at least the C-2 position to change the environment of the formulation. This penetration profile can be improved by using spin labels bound in the polar head group region, by filling in all points from C-3 to C-16, and by performing X-ray diffraction experiments on the same samples to obtain a more accurate estimate of the overall matrix thickness. Nevertheless, the essential features are clear, stearic acid spin-labels provide a means of estimating system heterogeneity, because they are randomly distributed in the plane of the matrix, position themselves so that the α -carbon of the fatty acyl chain is aligned with the head group region of the lipid matrix, and faithfully reflect the degree of orientational order and dynamics of the lipid molecules. The observed decay of S can be

related to the permeability properties of the system, because it is known that the EPR signal of the nitroxide group disappears almost instantaneously when the paramagnetic moiety is located at the polar interface of a lipid matrix. This observation is reinforced by the results obtained with the stearic acid spin probes (**Figure 4**). **Figure 4** shows representative EPR spectra of fomblin[®] HC/04 (relative molecular mass = 1500; viscosity index: 60) labelled with 12- and 7-doxyl stearic acids in the presence of a chlorinated glycoluril (S-330) control and exposed to different concentrations of half-mustard. It is well known that compounds containing a chloroamide group are generally preferred. S-330 provides an efficient antivesicant, which is characterized by its high efficiency and long protective times. One possible mechanism is that S-330 produces sufficient chloride ions to prevent the formation of the sulfonium ion intermediate, which is the active form of sulfur mustard. The graph in **Figure 4** illustrates the decay of the EPR integral signal (signal intensity in relative units) as a function of H-MG concentration. The decay of the EPR signal was dependent on the depth of penetration of the paramagnetic group into this heterogeneous matrix. The increase of H-MG concentration affects the penetration profile as shown in **Figure 4** for the four different spin-probes.

Fomblin HC/04 + S330 + 12-doxyl control

Figure 4 EPR spectra of a labelled reactive topical skin protectant with 12- and 7-doxyl in selected controls and exposed samples. The graph shows a plot of EPR signal integral (relative units) obtained from the labelled formulation as a function of H-MG concentrations for spin-label probes, 5-, 7-, 12-, and 16-doxyl stearic acids.

Spin probes only indirectly reflect the ordering of the host system. What information about the molecular architecture of this heterogeneous system can be deduced from these experiments? These labelled-formulations exhibit very little anisotropy (i.e. their magnitude and sign depend on the orientation of the radical with respect to the applied magnetic field) when hydrated with distilled water. Addition of non-electrolytes such as sucrose has no effect, but the addition of salt results in a large increase in EPR spectral anisotropy. This effect is thus one of charge, not of osmotic or vapour pressure. It has been shown to be owing to the cation and to depend on the cation valency. The order of effectiveness in promoting spectral anisotropy is $\text{NaCl} = \text{KCl} = \text{LiCl} < \text{MgCl}_2$, whereas the chloride, thiocyanate and sulfate salts of the same cation were equal in effectiveness. The cations act by reducing the surface charge density of the heterogeneous complex system, which consists of small particles and the lipid matrix. With the reduction in repulsion between groups, the ointment formulation can contract and achieve a higher degree of order. A net charge of the groups leads to molecular repulsion, an expansion of the formulation, and a decrease in EPR spectral anisotropy.

Vesicant agents of the 'mustard' type present some special features in their reaction mechanism(s). It is known that the mechanism involves, as a first step, the formation of a cyclic sulfonium ion and the release of chloride (Cl^-). This mechanism is illustrated for the

cases of half-mustard and sulfur mustard in **Scheme 2**. In addition, these vesicant agents are persistent agents, depending on pH and moisture. The mustard is hydrolysed to form HCl and thio-diglycol. Ointment formulation-incorporated spin probes are sensitive to the polarity and fluidity of their local environment. Cation binding, pH alterations, and the action of many substances perturb labelled formulations to yield characteristic changes in their respective EPR spectra. An adequate interpretation of EPR spectral changes in terms of the structure of the host matrix requires that alterations in fluidity and/or polarity be distinguished from changes in probe-probe interaction (e.g. dipole-dipole and electron-electron exchange broadening).

The spectral alterations noted upon addition of vesicant agents to a labelled formulation are caused by changes in (1) motion of the probe, (2) the polarity of the environment of the probe, (3) alteration in fluidity, and/or (4) the permeability profile. If the vesicant agent induces changes that involve radical interactions, the magnitude of the spectral alteration that depends on probe concentration will disappear.

EPR/Spin Trapping

EPR spin trapping techniques have successfully been applied to determine and identify free radical intermediates in biology and toxicology. Spin trapping allows

Scheme 2

one to determine if short-lived free radicals are involved as reaction intermediates by scavenging the reactive radical to produce more stable nitroxide radicals. This technique involves reaction of the initially generated radical (itself either too short-lived or of too low a concentration to directly detect) with an added organic compound, known as spin trap, to generate stable radical adducts from whose EPR spectra information about the original radical may be obtained.

Two kinds of spin traps have been developed, nitrones and nitroso compounds. **Figure 5** illustrates the most common commercially available traps. Nitrones are the spin traps of choice for the study of oxygen-centred radicals. The most popular nitron traps identified in **Figure 5** have a β -hydrogen that can provide considerable information about the radical trapped. However, some information is lost using these nitrones because the trapped radical adds to a carbon adjacent to the nitrogen.

Nitroso compounds can provide more information than nitrones as the radical to be trapped adds to the nitroso nitrogen, and, therefore, more information about the hyperfine splitting parameters is obtained.

In Vivo Spin Trapping of Oxygen-Centred Radicals

Nitrones have emerged as the most popular spin traps for biological applications, and out of several nitron spin traps, the cyclic 5,5-dimethyl-1-pyrroline *N*-oxide (DMPO) has received most attention, since it yields distinct and characteristic adducts with superoxide radical anion ($O_2^{\bullet-}$) and hydroxyl radical ($\bullet OH$). The use of DMPO as a probe for oxyradical generation in biology systems is not without limitations as high concentrations of DMPO have been suggested to have serious toxic

Figure 5 Names, structural formulae and relative molecular mass of the most common spin trapping agents commercially available.

effects on biological tissue. A low concentration of DMPO (10 mM) was used to detect free radical generation in hearts with ischaemia/reperfusion insult. **Figure 6** shows a scheme of a typical spin trapping experiment in an isolated heart. In the effluent immediately after reperfusion, DMPO-OOH, the superoxide spin adduct of DMPO, was obtained. DMPO at a 10 mM concentration range did not interfere with the left ventricular (LV) function during the control perfusion period. Enzyme leakage from hearts also supported non-toxicity findings of DMPO at 10 mM, confirming that the DMPO superoxide adduct is genuine evidence of the generation of superoxide upon reperfusion and is

not an artificial generation owing to the cytotoxicity of DMPO.

Furthermore, application of the spin trapping technique in intact animals requires an understanding of the stability of the spin traps and the spin adducts *in vivo*. A class of α -phosphorus-containing DMPO analogues, 5-(diethoxyphosphoryl)-5-methyl-1-pyrroline *N*-oxide (DEPMPO) has been synthesized and characterized for the generation of superoxide during the reperfusion of ischaemic isolated hearts. DEPMPO can trap and form a stable adduct for both $\cdot\text{OH}$ as DEPMPO-OH, and $\text{O}_2^{\cdot-}$, as DEPMPO-OOH, giving EPR spectra that are characteristic of each. Thus, unlike DMPO, DEPMPO can be used to distinguish between superoxide dependent and independent mechanisms that lead to the hydroxyl radical. DEPMPO is a good candidate for trapping radicals in functioning biological systems, and represents an improvement over the commonly used trap DMPO.

A very important aspect of spin trapping is to positively identifying the radicals under study. This assignment requires a knowledge of how certain features of the structure of the trapped radical influence the EPR spectrum of the spin adduct. Sometimes it is very difficult to determine unambiguously the precise structure of the spin adduct from the EPR signal obtained. Isotopic substitution EPR experiments are recommended in an attempt to identify the observed adducts. The strategy is that the unpaired electron in a radical interacts with the nucleus of the atom it orbits, and the spin of the nucleus determines the number of lines or peaks in the spectrum. For example, ^{13}C has a nuclear spin of $\frac{1}{2}$ while ^{12}C has no spin. An unpaired electron, which is associated with atoms having no spin, will exhibit an EPR spectrum containing only a single line. The spin of the nucleus influences the resonance of the unpaired electron so that the EPR resonance splits into two or more lines. The number of EPR resonance observed is equal to $2I + 1$, where I is the nuclear spin. A practical example using this concept follows. When human monocyte cells were exposed to 2-chloroethyl ethyl sulfide (H-MG) in the presence of the nitroso spin trap MNP, an EPR signal consisting mainly of a primary triplet was observed (**Figure 7a**). The complexity of the EPR spectrum suggested the trapping of a hydrogen-abstraction radical of polypeptide molecules. To verify the assignment, ^{13}C -labelled versions (at the C_2 amino acids) of human tumour necrosis factor- α (TNF- α) were reacted with H-MG in the presence of MNP. The resulting EPR spectrum (**Figure 7b**) was detected and simulated using five different hyperfine coupling constants, indicating the presence of an MNP- ^{13}C -centred adduct. Therefore, the spin trapping technique, properly applied, leaves no doubt about the nature of the radical or the intensity and duration of its production in biological systems.

Spin trapping method of isolated heart

Figure 6 Scheme of a typical spin trapping experiment in an isolated heart. Coronary effluents are collected and immediately frozen in liquid N_2 to prevent spin adduct decay. Frozen samples are thawed just before EPR measurement and EPR spectra are recorded using 160 or 250 μL flat cells. Typical spectrometer conditions are as follows: magnetic field 3350 G, power 8 mW, response 0.3 s, modulation amplitude 1.0–1.25 G, receiver gain 6.5×10^3 , sweep time 2 min, modulation frequency 100 kHz and temperature 23–28 $^\circ\text{C}$.

Figure 7 (a) EPR spectrum of MNP-adducts observed when THP-1 (monocyte cells) suspensions were exposed to H-MG (2×10^{-4} M) in the presence of MNP (7 mg). The magnetic field was set at 3350 G, microwave power 10 mW, modulation amplitude 8 G, microwave frequency 9.474 GHz. (b) EPR spectrum of the MNP adduct of ^{13}C -labelled serine $^{13}\text{C}_2$ amino acid generated by H-MG via a hydrogen atom abstraction mechanism. Computer simulation using the EPR parameters is given in the box.

EPR/Spin Trapping in Toxicology

The involvement of reactive intermediate species (RIS) in chemical agent toxicity could be also investigated using EPR/spin trapping techniques. For example, toxic oedemagenic gases, such as phosgene (OCCl_2), bis(trifluoromethyl)disulfide (TFD) and perfluoroisobutylene (PFIB), can be studied by spin trapping. Two types of apparatus that have proved useful for these experiments are shown in **Figure 8**. They consist of a 'tube' which connects via a 7/25 tapered ground-glass joint to a Wilmad EPR 'flat cell' (**Figure 8a**) and a 'U' tube which also with a tapered ground-glass joint to a Wilmad 'flat cell' (**Figure 8b**). In a typical experiment, one positions the tube or the 'U' tube vertically and a solution of the spin trap is placed in one chamber. The chambers are stoppered with rubber septa through which long ($\sim \#8$) syringe needles are inserted. The gas radical producers are then passed through the spin trap solution for 15–20 min. For deoxygenating purposes, bubbling purified nitrogen or argon gas through the solution is sufficient. The excess of gas can escape through a small syringe needle, as indicated in **Figure 8**. When gassing is complete the system is stoppered and the contents of the tubes and sample cell are thoroughly mixed and shaken into the EPR flat cell, which is inserted into the microwave cavity of the EPR spectrometer. Relatively simple modifications of this basic experimental design allow the study of other toxic chemicals. Highly reactive intermediate species of

Inset: spectral parameters for ^{13}C -phosgene obtained from the observed nitron spin adducts.

phosgene have been identified by adding ^{13}C -labelled phosgene into a PBN solution in benzene (**Figure 9**).

EPR/spin trapping can be used in the study of reactive intermediate species in a wide range of biological and toxicological systems. This technique allows the identification of radical species [and hence their mechanism(s) of production], and the indirect and real-time observation and quantification of radical reactions. To summarize, spin trapping is a powerful technique for the indirect EPR observation of many reactive free radicals. More ideas for dealing with this technique are well documented and discussed in reviews by Janzen, Anderson Evans, Mason, Thornalley and Buettner.

Introduction

Spectroscopy is the key to unlocking the information in starlight. Stellar spectra show a variety of absorption lines which allow a rapid classification of stars in a spectral sequence. This sequence reflects the variations in physical conditions (density, temperature, pressure, size, luminosity) between different stars. The strength of stellar absorption lines relative to the continuum can also be used in a simple way to determine the abundances of the elements in the stellar photosphere and thereby to probe the chemical evolution of the galaxy. Further, the precise wavelength position of spectral lines is a measure of the dynamics of stars and this has been used in recent years to establish the presence of a massive black hole in the centre of our galaxy and the presence of planets around other stars than the Sun.

Stellar Classification

All stellar spectra show absorption lines due to a variety of species. For the Sun, these were first discovered by Joseph von Fraunhofer in the early 1800s. A sample of stellar spectra is shown in **Figure 1**. The patterns in these lines allow stellar spectra to be grouped in a classification scheme. Depending on the spectral characteristics, stars are designated by a letter from the sequence O, B, A, F, G, K, and M. This spectral sequence is summarized in **Table 1**. Since temperature controls ionization and excitation of the atoms, this spectral classification basically reflects a temperature sequence. This temperature sequence is also obvious from the colours of stars.

The strength of an absorption line is a measure of the opacity in the line compared with that in the continuum. For A stars, which have surface temperatures around 10 000 K, the $n = 2$ level of hydrogen can be excited and, because H is by far the most abundant element in (almost) all stars, the opacity and hence the visual region of the spectrum are dominated by absorption out of these levels giving rise to prominent Balmer lines (**Figure 1**). For higher stellar surface temperatures (e.g. O stars), the fraction of the H atoms excited to the $n = 3$ level – which provide the continuum opacity in the visible – increases more rapidly than that in the $n = 2$ level. As a result, the strength of the lines relative to the continuum decreases

(**Figure 1** and **Table 1**). For the hottest stars, H is completely ionized and Thompson scattering by free electrons now dominates the continuum opacity. Lines of helium, which has a higher ionization potential, are still present. Of course, these He lines, which originate from levels much higher in energy than the ionization potential of hydrogen, require high stellar surface temperatures for their excitation. For stars much cooler than A, the H^- ion provides the continuum opacity. Because the population of the levels leading to Balmer absorption of hydrogen becomes very small in such cool stars, the strength of the H lines decreases relative to the continuum. Various trace elements with lower energy levels now take over the spectrum (**Figure 1** and **Table 1**). For the coolest K and M stars, most of the metals are neutral and molecules can survive in the stellar photosphere. Lines from these species will dominate the spectral appearance.

In addition to this spectral class, stars are also characterized by a luminosity parameter. This luminosity classification is made on the basis of the width of spectral lines. **Table 2** summarizes this classification. The width of spectral lines increases as the gas pressure increases. This so-called pressure broadening is due to the perturbation of atomic energy levels by other, nearby species. The physically largest stars have the lowest surface densities and pressures. Lines from these stars are therefore broader than from smaller stars (**Figure 1** and **Table 2**). This difference in size, which results in a difference in stellar luminosity, has led to the naming scheme from supergiants to dwarfs.

Stellar classification of a spectrum is actually based upon the intensity ratio of pairs of lines which are sensitive to temperature or luminosity. The lines used depend on the appropriate spectral type. This provides a straightforward way to classify stellar spectra and to determine rapidly the physical conditions in the stellar photosphere, including density, temperature, pressure, luminosity and size.

While these spectral and luminosity classes can be used to classify most stars, there is in addition a bewildering collection of stars with spectra which deviate in various respects. Generally, these variations reflect differences in the elemental abundances in the photospheres of these stars. Most stars have abundances very similar to the Sun. However, deep in the interior of each star, nucleosynthesis converts hydrogen and helium into heavier elements such

Table 1 Spectral types

<i>Spectral class</i> ^a	<i>T_{eff}</i> ^b (K)	<i>Colour</i>	<i>Spectral characteristics</i>
O	> 30 000	Bluish white	Relatively few lines. He ⁺ lines dominate
B	10 000–30 000	Bluish white	More lines; neutral He lines dominate; hydrogen Balmer lines developing
A	7500–10 000	White	Very strong hydrogen Balmer lines, decreasing later; Ca ⁺ line appears
F	6000–7500	White	Hydrogen Balmer lines and ionized metal lines declining; neutral metal lines increasing
G	5000–6000	Yellow	Many metal lines; lines of Ca ⁺ strong; neutral metal lines continue to increase
K	3500–5000	Reddish	Molecular bands appear; neutral metal lines dominate
M	2500–3500	Red	Neutral metal lines strong; molecular bands dominate

^aEach spectral class is subdivided into subclasses ranging from 0 to 9 with 0 the hottest and 9 the coolest type in the class.

^bApproximate photospheric temperature range for main sequence stars.

Table 2 Luminosity classes^a

<i>Luminosity class</i>	<i>Star type</i>
I	Supergiants
II	Bright giants
III	Giants
IV	Subgiants
V	Main sequence ^b
VI	Subdwarfs
VII	White dwarfs

^aAlong this sequence, the width of spectral lines increases from supergiants to white dwarfs.

^bMain sequence stars are also known as dwarfs.

Table 3 Additional spectral types

<i>Name</i>	<i>Spectral class</i>	<i>Spectral characteristics</i>
Carbon stars	C	Strong CN bands and C ₂ bands
Heavy metal stars	S	ZrO bands
Wolf Rayet stars	WN	N ²⁺ and N ³⁺ emission lines
	WC	Ionized carbon and oxygen lines
Hot emission line stars	Of, Be, Ae	Bright hydrogen emission lines

the star. Generally, this is done by measuring the strength of spectral lines relative to the continuum, the so-called equivalent width. The relationship between the equivalent width and the number of absorbers is called the curve of growth in stellar spectroscopy. For weak lines, the equivalent width is directly proportional to the number of absorbers. When the intrinsic strength of a line is larger or the number of absorbers is larger, the centre of the line saturates and the equivalent width becomes almost independent of the number of absorbing particles. For very strong lines or very large number of absorbers, absorption in the wings of the line becomes important and the equivalent width of the line will increase proportionally to the square root of the number of absorbers present. Stellar spectra contain many lines of a given element with known intrinsic strength. These can be used to construct an empirical curve of growth for that element. Comparison of such curves of growth for different elements yields then the relative elemental abundances. **Figure 2** shows an example for iron and titanium lines in the Sun. Similarly, we can compare the curves of growth for other stars with that for the Sun and determine elemental abundances for these stars relative to solar.

This semiempirical method is fairly straightforward but does assume that all the lines and the continuum involved are formed in the same region. Moreover, these

Figure 2 Empirical curve of growth for solar Fe I and Ti I lines. The y-axis is the equivalent width (line strength relative to the continuum) and the x-axis is based on the oscillator strength of the transition.

line formation regions would have to have similar physical conditions in all stars. This is not always justified. Furthermore, cool stars have very crowded spectral regions where line overlap is a severe problem. In these cases, detailed modelling is a prerequisite for the determination of accurate stellar abundances. Sophisticated techniques have been developed which model in detail

Figure 3 Observations of the star BD +75° 325'; (thick solid line) obtained by the Goddard high-resolution spectrometer on board the Hubble space telescope, showing numerous iron and nickel lines in various ionization stages. These data are compared with model atmosphere spectra. The thin solid line is the best fit model for an iron abundance of 4×10^{-4} and the dotted line is for solar abundances (4×10^{-5}). A solar iron-to-nickel ratio has been assumed in both models. Reproduced with permission from Lanz T, Hubeny I, and Heap SR (1997) *Astrophysical Journal* 485: 843.

the physical structure of the stellar photosphere and its interaction with light. These models solve the equation of statistical equilibrium, regulating the individual level populations, the equation for hydrostatic equilibrium, governing the stellar pressure structure, and the radiative transfer equations describing the absorption and emission of light in the stellar photosphere. Comparison of models calculated for a variety of abundances with the observations allows the determination of the elemental abundances. In general, good agreement between models and observations can be obtained (Figure 3).

Analyses of this kind have shown that nearly all stars have very similar elemental compositions. The spectra of some stars, however, reveal much lower abundances than in the Sun. These so-called subdwarfs are metal-poor by factors up to 500. These compositional variations are correlated with the mass, age and dynamics of the stars within the Milky Way. The stars that formed first have the lowest elemental abundances. As those stars evolved – the more massive ones more rapidly than the less massive ones – they ‘polluted’ the interstellar medium with the nucleosynthetic products formed in their interiors either through a gentle wind (low-mass stars) or through a violent supernova explosion (massive stars). In this way, later generations of stars are formed from gas with higher elemental abundances. It is this elemental enrichment that drives the evolution of the Milky Way and other galaxies.

Stellar Dynamics

In addition to spectral and luminosity classification and abundance determination, stellar spectra also provide the radial motion of the absorbing gas through the Doppler shift. High-resolution spectra can thus provide information on stellar outflows in K and M giants, carbon stars, Of, Be and Ae emission line stars and Wolf Rayet stars. In general, the velocity information available in stellar spectra can be used to probe the dynamics of stars in the galaxy. For example, this technique has been used to trace the dynamics of stars in the centre of our galaxy. The derived velocity law implies a supermassive object in the centre of the galaxy with 3×10^6 solar masses. This provides strong evidence for the presence of a massive black hole in the centre of the Milky Way.

By monitoring radial velocities over a long period, stellar spectroscopy can also be used to search for stellar companions, be they binary stars, brown dwarfs (stellar-like companions which are not massive enough to start hydrogen burning in their interiors) or planets. In recent years, new techniques have been developed to search for planets orbiting solar-type stars using Doppler shifts. In order to eliminate systematic wavelength shifts, the spectra are calibrated either by passing the stellar light through iodine gas or by using stable, fibre-fed spectrometers with

Figure 4 Typical cross-correlation function used to measure the radial velocity. This figure represents the mean of the spectral lines of the star 51 Peg. The position of the Gaussian function fitted (solid line) is a precise measurement of the Doppler shift to an accuracy of about 15 m s^{-1} . The width of the cross-correlation function reflects the star's rotational velocity. Reproduced with permission of Macmillan Magazines Ltd. from Mayor M and Queloz D (1995) *Nature* 378: 355.

simultaneous Th–Ar wavelength calibration. In long-term monitoring programmes, radial velocities of stars can then be measured with an accuracy of about 15 m s^{-1} , using a cross-correlation technique which concentrates the Doppler information for some 5000 stellar absorption lines (Figure 4). For comparison, the wobble introduced in the Sun's radial motion by Jupiter is about 13 m s^{-1} . The planetary companions found so far in this way have masses in the range 0.5–10 Jupiter masses and orbits with solar system dimensions. In this way, stellar spectroscopy has allowed us to complete the ‘Copernican’ revolution.

The Model

Ionization via 70 eV electronic impact brings about a large number of Franck–Condon transitions to many electronic states of the ion. The molecular ion then undergoes internal conversions to its lowest electronic state owing to the existence of very fast and efficient radiationless transitions which themselves result from the presence of numerous crossings between potential energy surfaces. **Figure 1** shows a calculated set of potential energy curves for the $\text{F}_2^{+\bullet}$ molecular ion.

This picture gives some idea of the complexity to be expected, for example, in the case of the isoelectronic ion $\text{CH}_3\text{CH}_3^{+\bullet}$. For polyatomic molecular ions, the pattern of surface crossings is extremely complicated because the density of electronic states is much higher than that detected by photoelectron spectroscopy and because of the number of nuclear degrees of freedom. In a polyatomic system, the sequence of radiationless transitions results from the presence of conical intersections and is usually over after about 10^{-13} s. Once in the electronic ground state, vibrational energy is assumed to be redistributed (randomized) throughout the different vibrational degrees of freedom on a timescale short with

respect to the reaction lifetime. When it fragments, the vibrationally excited molecular ion has forgotten its initial conditions. It undergoes a series of competing, consecutive, unimolecular reactions that can be described by a statistical theory. The theory is known under two acronyms, viz. RRKM (after Rice, Ramsperger, Kassel and Marcus) and QET (for quasi-equilibrium theory, as suggested by Rosenstock, Wahrhaftig and Eyring).

Probably the most convincing argument for the validity of a statistical approach comes from the independence of the fragmentation pattern with respect to the way energy is delivered. Except in rare cases, there is no correlation between the breakdown diagram determined from photoion–photoelectron coincidence (PIPECO) experiments and the photoelectron spectrum. In addition, when the molecular ion (e.g. $\text{C}_2\text{H}_4^{+\bullet}$) can be prepared by a collision process (e.g. $\text{C}_2\text{H}_2^{+\bullet} + \text{H}_2$ or $\text{C}^+ + \text{CH}_4$), the fragmentation ratios (e.g. $\text{C}_2\text{H}_4^{+\bullet} : \text{C}_2\text{H}_3^+ : \text{C}_2\text{H}_2^{+\bullet}$) at a given internal energy are usually found to be equal within the experimental error to those obtained when the system is prepared by photon impact (see **Figure 2**).

These observations imply that the dissociation rate constants are smooth, monotonically increasing functions of the internal energy E of the decaying molecular ion alone, irrespective of the way energy is delivered to the molecule, and do not depend on the electronic and vibrational quantum numbers that specify a particular molecular state. The criterion of validity of a statistical treatment (viz. that all of the properties of the system be completely characterized by a single parameter, its internal energy) is thus fulfilled. Exceptions to this pattern of behaviour exist, but they are rare. Many authors have attempted to develop a ‘mode-selective chemistry’, i.e. to promote reaction involving a chosen bond by excitation of that bond alone. These efforts have met with very limited success for unimolecular reactions, except in the case of van der Waals complexes where the coupling between the high-frequency intramolecular modes and the low-frequency intermolecular mode is weak.

Phase Space

In principle, the evolution of a molecular ion on its lowest potential energy surface is governed by the equations of classical (or quantum) mechanics. Consider a molecular ion made up of N atoms. Its evolution is known when we know the values of the $3N$ coordinates

Figure 1 Potential energy curves for the F_2^+ ion.

Figure 2 Top: photoelectron spectrum of ethylene. Bottom: breakdown graph of ethylene determined by photoion-photoelectron coincidence measurements. Triangles and filled circles: yields of $C_2H_2^+$ and $C_2H_3^+$ ions, respectively, obtained by collision experiments. The ground and excited electronic states of the $C_2H_4^+$ ion are denoted by X, A, B and C.

and of the $3N$ conjugated momenta (related to generalized velocities) as a function of time. This information can be graphically represented as a trajectory in a $6N$ -dimensional hyperspace, called the phase space.

Randomness is not accounted for by the deterministic classical equations. Indeed, at low internal energies, the nuclear trajectories appear regular (quasi-periodic). The molecular ion can then be described as a set of $(3N-6)$ harmonic or anharmonic but separable oscillators to which, if relevant, one, two or three overall rotations have to be added. Only a small fraction of the available phase space is then visited. However, at higher internal energies, the usual model of a collection of $(3N-6)$ independent oscillators breaks down. The nuclei then carry out extremely complicated trajectories and the fraction of phase space visited increases dramatically. If, for all trajectories characterized by a given energy, this fraction reaches a value of 100%, the system is declared 'ergodic' and statistical mechanics then generates exact equations. In technical terms, one has reached a state of microcanonical equilibrium. Even when the limit of 100% is not reached, useful equations can be derived from a statistical treatment, and this is the origin of the denomination 'quasi-equilibrium theory' adopted by Rosenstock and colleagues.

There are essentially two explanations that account for the success of the statistical approach.

Efficient Intramolecular Vibrational Energy Redistribution (IVR)

The potential energy surface of the ground electronic state of the molecular ion is assumed to be so anharmonic that the various vibrational degrees of freedom are strongly coupled. IVR is then expected to be rapid compared with the timescale of the reaction. When it follows photon excitation or electron impact, IVR is a sequential process. First, after a time of the order of 10^{-13} s, energy is redistributed among the optically active modes. The second step (for which a timescale of the order of about 10^{-11} s can be proposed) consists of an energy exchange from symmetric to antisymmetric modes by anharmonic coupling (e.g. Fermi resonances). Efficient IVR implies that each individual nuclear trajectory has visited most parts of the available phase space before dissociating. This case is represented schematically in **Figure 3a**. The isolated molecular ion is then expected to reach spontaneously the ergodic limit under collision-free conditions. IVR is known to be inefficient in the case of van der Waals complexes (and probably also in the case of weakly bonded species) because of the disparity between the high intramolecular frequencies and the low intermolecular ones.

Randomness of the Initial Conditions

For thermal reactions, the success of the statistical approach can be explained by invoking the impossibility of specifying

the initial conditions if energy is delivered by molecular collisions. As shown in **Figure 3b**, even if each individual trajectory does not meet the requirements of ergodicity, an average over a large number of randomly distributed initial conditions will lead to a quasi-uniform sampling of the available phase space. For mass spectrometric experiments, this argument is apparently irrelevant. However, it should be noted that the initial conditions are also poorly defined, even if the experiment is carried out under collision-free conditions. As mentioned in the first section, the initial conditions are determined by the conversion of electronic into vibrational energy via a cascade of radiationless transitions to the ground state of the molecular ion. As suggested by **Figure 1**, the pattern of surface crossings can be extremely complicated in a polyatomic system. Each process ends up at a different phase-space cell of the reacting ground-state ion. In addition, autoionization (a process in the course of which internal energy of the ionic core is transferred to a Rydberg electron, which is then ejected) generates a molecular ion characterized by its particular initial distribution of the vibrational energy. All of these processes lead to a pattern where the initial conditions are scattered at various positions in phase space. The averaging over these widely different initial conditions ensures the validity of a statistical approach.

The Transition State

The concept of transition state plays an essential role in the theory because it provides a simple, compact, but approximate description of the dynamics of the reaction. It can be defined in various ways. Essentially, one assumes that there exists some critical configuration of the reacting molecule, called the transition state, such that once the molecule has reached this configuration, it will irreversibly proceed on to products. (The term activated complex is sometimes used, but it is best to restrict its use to bimolecular reactions.)

The transition state, defined as it is as a point of no return, is often associated with the top of a potential energy barrier; that is, it is defined as a saddle point with a negative curvature of its potential energy surface along the reaction coordinate and hence with a single imaginary frequency. However, many molecular ions dissociate with no reverse activation energy barrier.

The transition state is not a stable molecule but a fictitious entity obtained after removal of the reaction coordinate, thus having one degree of freedom less than the reactant. Its best definition is that of a dividing surface in phase space. Reactant and products are assumed to be separated by a surface whose crossing is assumed to be irreversible (i.e. having crossed it once, the trajectories terminate as products without recrossing the surface backwards). The reaction is modelled as a flux through this

Figure 3 (a) A single ergodic trajectory visits a substantial part of phase space. (b) A swarm of nonergodic trajectories originating from widely different initial conditions fills up the entire phase space.

Figure 4 Potential energy surface for a unimolecular fragmentation, with the dividing surface separating the reactant from the products.

dividing surface and its rate is measured by counting the number of times the surface is crossed per second (see Figure 4).

The RRKM-QET Equation

Consider a microcanonical ensemble of molecular ions with an energy between E and $E + \delta E$. The total number of quantum states available to members of the ensemble is denoted $\rho(E)\delta E$, where the function $\rho(E)$ is called the density of states. Of these, a certain fraction corresponds to transition states. The rate constant $k(E)$ is proportional to the ratio of these two quantities. Many unknown parameters defining the transition state cancel out in the final expression, which reads simply

$$k(E) = \sigma \int_0^{E-E_0} \rho^\ddagger(E') dE' / b\rho(E) = \sigma N^\ddagger(E-E_0) / b\rho(E) \quad [1]$$

where $N^\ddagger$ denotes the number of accessible quantum states of the transition state, i.e. those having a potential energy E_0 and a translational kinetic energy ε in the reaction coordinate, with the remainder $(E - E_0 - \varepsilon)$ in the bound degrees of freedom, and σ is the reaction path degeneracy, i.e. the number of equivalent paths leading from the reactant to the products. (The quantities affixed with a double dagger refer to the transition state, which has one degree of freedom less than the reactant.)

At threshold (i.e. when $E = E_0$), $N^\ddagger(0) = 1$. Thus, the minimum rate is in principle equal to $1/b\rho(E_0)$. However, when the internal energy E is equal to, or even is slightly less than the barrier, then the reaction proceeds via tunnelling and a transmission probability κ is then inserted into eqn [1]. Isotope effects are then to be expected. When the shape of the barrier can be described by an inverted parabola, a simple expression can be derived for the transmission coefficient:

$$k(E) = \frac{\exp[2\pi(E - E_0)/bv^\ddagger]}{1 + \exp[2\pi(E - E_0)/bv^\ddagger]} \quad [2]$$

where $v^\ddagger$ is the modulus of the imaginary frequency of the saddle point. Expressions for more complicated, unsymmetrical barriers are also available.

Practical Calculations

There exists a computer algorithm (developed by Beyer and Swinehart) for counting all the possible combinations of the vibrational quantum numbers that are consistent with a specified value of the internal energy, even for a collection of anharmonic (but independent) oscillators.

Alternatively, analytical expressions for the energy-level densities can be obtained by inverse Laplace transformation of the corresponding partition function. This works well for the rotational degrees of freedom. For example, for a single rotor having a symmetry number equal to σ , one has simply (except at very low energies):

$$\rho(E) = \sigma^{-1}(BE)^{-1/2} \quad [3]$$

where B is the rotational constant.

However, for a collection of oscillators, the set of energy levels is not dense enough and the energy-level density has to be numerically calculated by the steepest-descent method implemented by Forst. Nevertheless, an approximate closed-form expression involving an empirical correction for the effect of the zero-point vibrational energy has been developed by Whitten and Rabinovitch. For a system of n oscillators having frequencies ν_i , one has:

$$\rho(E) = \frac{(E + aE_z)^{n-1}}{(n-1)! \prod_{i=1}^n b\nu_i} \quad [4]$$

where E_z is the total zero-point energy and a is an empirical parameter that usually ranges between 0.7 and 0.98. This formula leads to satisfactory results for the calculation of the denominator of eqn [1]. For its numerator, a direct count of the sum of states $N^\ddagger(E - E_0)$ is preferable, because at lower energies the vibrational levels are usually too widely spaced for a classical or semiclassical approximation to work.

The numerical values of the frequencies and moments of inertia needed for an actual calculation can be obtained from commonly used quantum-chemistry programs. This is the only possibility for the frequencies of the transition state.

The role played by the overall rotations raises a difficult problem. The constraint of angular momentum conservation prevents certain rotational degrees from getting involved in randomization. Very often, the transition state is approximated as a symmetric top, with two equal moments of inertia. It is then usually assumed—possibly incorrectly—that the degenerate two-dimensional external rotation is unable to couple significantly with the vibrational degrees of freedom, whereas the rotation about the reaction coordinate is able to exchange energy with them. However, although unavailable for randomization, the rotational energy stored in the degenerate external two-dimensional rotation modifies the radial potential and gives rise to an effective potential characterized by a centrifugal barrier.

More Elaborate Statistical Models

It has been found useful to introduce new concepts and methods, particularly in the study of reactions for which no potential barrier is encountered along the reaction coordinate, a case often encountered in the dissociation of molecular ions. In such a case, the conservation of the orbital angular momentum during the reaction process has important consequences.

Microcanonical Variational Transition State Theory (VTST)

If the transition state is defined as a structure denoting an unstable equilibrium between the reactant and the products,

then any point of its phase space having a nonzero velocity in the forward direction will react. However, this criterion is oversimplified: the condition is necessary but not sufficient. After having left the transition state, some trajectories may return to cross it again. Hence, the rate constant calculated by the transition state theory is an overestimate of the exact value. (This conclusion has been challenged, however, when energy is selectively delivered to the system, as in laser light excitation.) Leaving the controversial cases aside for deeper scrutiny, it follows that the best choice for the transition state is the one that minimizes the calculated rate constant. Therefore, in VTST, the numerator of eqn [1] is written as $N^\ddagger[E - V_{\text{eff}}(R^\ddagger)]$, where $V_{\text{eff}}(R)$ denotes the effective potential for motion along the reaction coordinate R (usually, the sum of the actual and a centrifugal potential), and where $R^\ddagger$ denotes the position of the dividing surface that minimizes $N^\ddagger$.

Transition State Switching

The rate constant does not necessarily admit a unique minimum. Thus, several transition states may simultaneously exist along the reaction coordinate with characteristics depending on the energy and angular momentum. For example, a tight transition state may be followed by an orbiting complex. The former determines the magnitude of the rate constant, whereas the latter controls the translational, rotational and vibrational energy distributions of the products.

Bottlenecks

This term is often encountered, but is used with two different connotations. First, it may describe an impediment to IVR (resulting, for example, from the presence of a heavy atom or from a disparity in the frequencies). Alternatively, it may describe a throttling of the reactive flux (i.e. a new kind of transition state) due, for example, to a region of strong curvature of the reaction path resulting, for example, from a detour around a conical intersection between two potential energy surfaces.

The Statistical Adiabatic Channel Model (SACM)

Troe and Quack have defined reaction channels as a set of potential energy curves obtained by connecting the vibration-rotational states of the reactant to those of the pair of products along the reaction coordinate. (This procedure is referred to as an adiabatic correlation.) Barriers arise when imposing conservation of the orbital angular momentum during the reaction process to the transitional modes (i.e. the vibrational bending modes that correlate with rotations or orbital motion of the fragments). A channel is said to be open when its potential energy curve never exceeds the available internal energy E . No reference to a transition state is made in

this theory. The rate constant now depends on two parameters, viz. the internal energy E and the total angular momentum J . Its expression is remarkably similar to the RRKM-QET equation:

$$k(E, J) = \frac{N^*(E, J)}{b\rho(E, J)} \quad [5]$$

where $N^*(E, J)$ is now defined as the total number of open channels.

The Orbiting Transition State Phase Space Theory (OTS/PST)

The unimolecular reactions of polyatomic ions are assumed to be governed by the long-range part of the potential. The principle of microscopic reversibility has been used by Klots to express the rate constant, not in terms of the properties of a transition state, but in terms of the cross section for association of fragments. The latter is then evaluated by the Langevin theory, which is based on the consideration of a long-range attractive potential (e.g. $-\alpha q^2/2R^4$). Alternatively, an orbiting transition state located at a centrifugal barrier has been reintroduced by Chesnavich and Bowers. In both cases, the density of states is no longer evaluated as a simple convolution between the vibrational and rotational parts, but by introducing restrictions resulting from the conservation of angular momentum. This theory often provides too large estimates for the rate constant.

Effective Number of States

Information theory shows that if the assumption of complete energy randomization breaks down, then eqn [1] remains valid provided it is interpreted as a ratio between an *effective* number of states divided by an *effective* density of states. Both the numerator and the denominator are then reduced (but not necessarily to the same extent) by a so-called entropy deficiency factor. A mechanism of cancellation of errors arises, which accounts for the success of the simple theory.

Nonadiabatic Reactions

Nonadiabatic reactions (i.e. those involving a change in the electronic state or structure) occur more frequently in mass spectrometry than is commonly thought. Surprisingly enough, statistical methods are found to be useful even in these cases.

Kinetic Energy Release Distributions (KERDs)

The internal energy in excess of the thermodynamic dissociation threshold is partitioned among the translational,

rotational and vibrational degrees of freedom of the pair of fragments. In the case of molecular ions, the translational kinetic energy release distribution (KERD) can be measured and its study is a precious source of information on the dynamics of the reaction. Indeed, it is a stronghold of the more elaborate statistical theories presented in the previous paragraph because the usual RRKM-QET theory is in principle not appropriate for such a study. The reason is that transition state theory concentrates on the behaviour of the system up to the dividing surface, whereas the product energy disposal is determined by the potential felt by the fragments as they separate. However, Marcus, Wardlaw and Klippenstein have proposed an extension that describes the evolution of the transitional modes along the reaction coordinate and that, at the same time, conserves angular momentum.

Phase space orbiting transition state theory works much better for the calculation of KERDs than for that of the rate constants, thereby demonstrating that the former are controlled by the long-range part of the potential, whereas the latter are governed by its shorter range. In addition, Klots has introduced a set of effective temperatures to parametrize the observed distributions. The SACM has also demonstrated its usefulness in the case of weakly bonded species.

The maximum entropy method and the associated surprisal theory are an outgrowth of information theory. They involve a comparison between the actual shape of the KERD and the hypothetical, most statistical, so-called 'prior distribution'. Two precious pieces of information can be derived from this comparison: (i) an identification of the constraint that operates on the dynamics and prevents it from being statistical and (ii) the magnitude of the entropy deficiency which can be related to the fraction of phase space effectively sampled by the transition state. Values of 75–80% have been obtained in the case of the halogenobenzene ions.

Concluding Remarks

It has often been remarked that the RRKM-QET theory can fit anything and predict nothing. To counter this criticism, many authors have multiplied skilful consistency checks (study of isotope effects, preparation of the ion via a bimolecular reaction or via charge reversal in addition to electron or photon impact, time-resolved studies all the way from the millisecond to the nanosecond timescales, etc.) and have removed arbitrariness via *ab initio* calculations of frequencies. However, it should be realized that ability to fit the experiments by no means implies that the theory is exact and that its basic assumptions (full energy randomization and existence of a good transition state) are fulfilled. It has been seen that eqn [1] cannot be grossly in error because of a

mechanism of cancellation of errors. In contradistinction, KERDs (for which the cancellation of errors does not work because they basically depend on the numerator only) provide a much better way to test the validity of the assumption of complete energy randomization than a study of fitted rate constants.

Stereochemical effects in mass spectrometry have been used for configurational assignment in numerous organic systems. The unsurpassed sensitivity of mass spectrometry and the possibility of interfacing the mass spectrometer with a variety of separating devices (most commonly gas chromatography–mass spectrometry (GCMS) and liquid chromatography–mass spectrometry (LCMS)) make it a most useful tool for structural assignment of minor constituents of complex mixtures, including stereochemical information. The mass spectral stereochemical effects may also be an important and useful tool in structural studies of gas-phase ions and in mechanistic investigations of their fragmentation processes.

Mass spectral stereochemical effects occur in the molecular radical cations $M^{+\bullet}$, obtained usually on electron ionization (EI), in protonated molecules MH^+ upon chemical ionization (CI) and other soft ionization techniques (fast atom bombardment (FAB), electrospray, thermospray), and, to a lesser extent, in negative ions. These effects are observed in the normal mass spectra and also by tandem mass spectrometric techniques (MS/MS).

The different mass spectral behaviour of stereoisomers (this term will not include enantiomers in this article) may be due either to the different thermochemical nature of the chemistry of their gas-phase ions, or it may result from the different kinetics of their reactions. These two aspects will be dealt with in the following sections.

Thermochemical Considerations

Electron Ionization

Small, often insignificant or within the experimental error, differences (in most reports below 0.1 eV) have been observed in the ionization energies of stereoisomers in a number of systems. The appearance energies of some specific fragment ions often show a more pronounced dependence on the configuration of stereoisomers. Lower energies have been reported for $[M-R]^+$ ions obtained from stereoisomers with higher enthalpies of formation in various dialkylcycloalkanes and in other more complex heterocyclic and polycyclic systems. The difference between the appearance energies could be quantitatively correlated with the difference in the enthalpies of

formation of the stereoisomers in several systems. The lower appearance energies of the thermochemically less stable stereoisomers have been attributed to the release of steric strain in the course of the fragmentation.

Since the early days of mass spectrometry it has been proposed, that the release of steric strain results, in many cases, in lower abundances of the molecular ions and in higher abundances of fragments in the EI mass spectra of the thermochemically less stable isomers in numerous systems. The differences between the mass spectra of stereoisomers in those systems are usually not large, and there are numerous exceptions which cast doubt on the reliability of this approach in real problems of configurational assignments.

Chemical Ionization

In contrast to the ionization energies, considerably different proton affinities and gas-phase basicities have been reported for a number of stereoisomeric difunctional compounds, which have an impact on their behaviour upon chemical ionization. For example, the gas-phase basicities of *cis*- and *trans*-2-amino-3-hydroxybicyclo[2.2.2]octanes 1c and 1t (Scheme 1) are 926 and 909 kJ mol⁻¹, respectively. The difference is attributed to the different interfunctional distance in the two stereoisomers (2.31 and 3.50 Å respectively) resulting from their different dihedral angles about the HOC–CNH₂ bond (30° and 150°). The effective intramolecular hydrogen bond (often termed proton bridging), which is possible in the MH^+

Scheme 1

Scheme 2

ion of the *cis*-amino alcohol 1c (Scheme 1), results in the higher gas-phase basicity of this stereoisomer.

A smaller difference ($4\text{--}5 \text{ kJ mol}^{-1}$) has been reported between the stereoisomeric *cis*- and *trans*-4-phenyl-1-alkoxycyclohexanols 2c and 2t (Scheme 2), and it has been attributed to proton bridging between the alkoxylic oxygen atom and the phenyl ring, which is possible only in the MH⁺ ions of 2c (Scheme 2).

Easy distinction between stereoisomers containing two or more basic sites may be achieved upon CI using selected reagent gases, based on the remarkable difference in their proton affinities and gas-phase basicities, due to the effectiveness of proton bridging. Thus, diesters with remote alkoxy-carbonyl groups (e.g. fumarates, mesaconates, *trans*-1,3- and 1,4-cyclohexane dicarboxylates) give rise to low abundance MH⁺ ions and to abundant $[\text{M} + \text{NH}_4]^+$ adduct ions upon NH₃-CI, because of the higher proton affinity of ammonia. On the other hand, the *cis* analogues with adjacent ester groups (e.g. maleates, citraconates, *cis*-1,3- and 1,4-cyclohexane dicarboxylates), which may undergo intramolecular proton bridging on protonation, afford abundant MH⁺ ions under NH₃-CI (Scheme 3).

Stabilization of the MH⁺ ions by intramolecular hydrogen bonding may be used as a simple tool in the configurational assignment of stereoisomeric diols, diesters and other difunctional analogues. Stereoisomers with adjacent basic functions afford abundant proton-bridged MH⁺ ions under CI conditions. Counterparts with remote functions, which cannot be stabilized by proton bridging, undergo fragmentation processes resulting in less abundant MH⁺ ions in their CI mass spectra. Typical examples are shown in Scheme 4, and many others have been reported.

The above stabilization effect is limited to systems such as 4 and 5 (Scheme 4), containing at least one

Scheme 3

functional group (e.g. OH, OR) which undergoes ready dissociation upon CI. Other systems, e.g. diesters, with functional groups that are stable under CI conditions, behave in a different manner. Protonated esters of aliphatic or cycloalkanoic acids exhibit a high degree of stability upon isobutane-CI. Protonation occurs at the carbonylic oxygen atom, and the 1,3-proton transfer to the alkoxy oxygen, that would enable alcohol elimination, is a symmetry forbidden process. The nonbridged MH⁺ ions of diesters, with two remote noninteracting alkoxy-carbonyl groups (e.g. *trans*-6) (Scheme 5), are stable (and consequently highly abundant) under isobutane-CI. On the other hand, stereoisomers, with adjacent ester groups (e.g. *cis*-6) (Scheme 5), undergo facile proton transfer between the two alkoxy-carbonyls *via* proton-bridged intermediates, resulting in the efficient elimination of ROH (Scheme 5). In the latter systems, the thermodynamically stabilized proton-bridged species are kinetically destabilized, resulting in less abundant MH⁺ ions.

Kinetic Considerations

A wide variety of fragmentation processes of the M^{•+} and MH⁺ ions obtained upon EI and CI involve formation of new bonds. Such unimolecular rearrangements take place via cyclic transition states. Molecular ions of stereoisomers often differ in the accessibility of the transition structures for fragmentation processes, which involve bond formation or concerted rupture of several bonds. Relatively large differences in the energy of activation of such processes may result in extreme cases in total suppression of particular pathways in one of the stereoisomers. A large number of systems have been reported that show

Scheme 4

Scheme 5

stereospecific fragmentation behaviour upon EI and CI. A limited number of typical examples will be given in the following.

Hydrogen Transfer

Elimination of H₂O from cycloalkanols and related processes

One of the early cases of stereospecific fragmentation processes of gas-phase ions was the EI-induced dehydration of stereoisomeric 4-substituted cyclohexanols. *Trans*-4-*t*-butyl- and -4-arylcyclohexanols 7t (Scheme 6) afford highly abundant $[M-H_2O]^+$ ions, which are

much less abundant in the mass spectra of the *cis* isomers 7c (Scheme 6). Similar stereospecificity has been also observed in the elimination of methanol and acetic acid from the corresponding methyl ethers and acetates. Deuterium labelling studies have shown that the H-atom from position 4 is abstracted in the course of the elimination of H₂O from the *trans*-alcohols, but not to an appreciable extent in the case of the *cis* isomers. The low energy H-transfer from the tertiary (and benzylic when R = aryl) position 4 to the hydroxy group is the stereospecific step in this fragmentation. The cyclic transition state of this H-transfer is attainable only in 7t (Scheme 6) in the boat conformation. The high stereospecificity of

Scheme 6

Scheme 7

this process indicates retention of the original structure in the molecular radical cation.

A similar stereospecific behaviour has also been observed in stereoisomeric 3-arylcyclohexanols and in their methyl ethers and acetates, but not in the 2-aryl analogues, which undergo cleavage of the $\text{C}_1\text{--C}_2$ bond prior to fragmentation, resulting in the loss of stereochemical information. Many additional systems have been shown to undergo EI-induced stereospecific eliminations of water and other neutral molecules, which may be applied in structural studies.

It is noteworthy that stereoisomeric cycloalkanols and their derivatives exhibit a lower degree of stereospecificity in their dissociation upon CI. Protonation occurs at the oxygen atom in these materials, and the concurrent

elimination, that takes place by a simple cleavage of the C--O bond, is governed by thermochemical factors.

Cycloalkylidene Acetates

The geometrically isomeric *E*- and *Z*-disubstituted cycloalkylidene acetates (e.g. *E*-8 and *Z*-8) exhibit a highly specific EI-induced loss of one of the two substituents R and R' at the two homoallylic positions, as shown in **Scheme 7**. The specific H-transfer from the allylic position adjacent to the carbonyl toward the carbonyl oxygen atom has been proposed as explanation for the stereospecificity of this process. These results enable easy distinction and configurational assignment of stereoisomers in analogous systems (including acyclic analogues), which is not straightforward by other

Scheme 8

spectroscopic methods. They also indicate that the rotation about the double bond in the $M^{\bullet+}$ ions must be slower than the H-transfer in this process.

McLafferty Rearrangement and Related Processes

The stereospecificity of the McLafferty rearrangement is exemplified by the different behaviour of *endo*- and *exo*-acetylnorbornanes *endo*-10 and *exo*-10 upon EI, shown in **Scheme 8**. The m/z 71 ion is abundant in the EI-mass spectrum of *endo*-10, but absent in that of *exo*-10. McLafferty rearrangement is the initial step in the formation of the m/z 71 ion with the involvement of the H-atom from position 6, which is in the proper distance from the carbonylic oxygen only in the *endo*-isomer.

Steric interactions in the cyclic transition structures for a hydrogen transfer result in a different abundance of the butene radical cation fragment, obtained from the diastereoisomeric unsaturated alcohols *erythro*-10 and *threo*-10. The higher energy of the transition state of *erythro*-10, due to the steric interaction of the methyl and R groups, results in a lower abundance of the fragment, as compared with the stereoisomeric *threo*-9 (see **Scheme 9**).

Alcohol Elimination from MH^+ Ions of Diesters upon CI and CID

It has been previously mentioned that MH^+ ions of diesters, with the two remote noninteracting alkoxy-carbonyl groups, are stable and consequently highly abundant under isobutane-CI. On the other hand, stereoisomers with adjacent ester groups undergo a facile proton transfer between the two alkoxy-carbonyls via proton bridged intermediates, resulting in the efficient elimination of ROH (**Scheme 5**). This behaviour enables easy distinction between stereoisomeric diesters by CI mass spectrometry, and also by CID measurements of MH^+ ions. CID mass spectra of the m/z 173 MH^+ ions

Scheme 9

of diethyl maleate Z-11 and fumarate E-11 exhibit an entirely different behaviour (**Scheme 10**): that of Z-11 shows an abundant m/z 127 $[MH-EtOH]^+$ ion which is absent in the spectrum of E-11, while that of E-11 exhibits abundant m/z 145 $[MH-C_2H_4]^+$ and m/z 117 $[MH-2C_2H_4]^+$ ions, which do not appear in the CID spectrum of Z-11.

These distinctive features of the CID spectra also enable structural assignments and quantitative relative abundance estimates of protonated maleate and fumarate ions, which are formed by mass spectral fragmentation of higher systems. For example, this method was used to determine that the retro-Diels–Alder (RDA) fragmentation of *cis*- and *trans*-2,3-diethoxycarbonyl-5,6,7,8-dibenzobicyclo[2.2.2]octanes 12 under $i-C_4H_{10}$ -CI and CH_4 -CI conditions is highly stereospecific, giving rise to protonated diethyl maleate and fumarate, respectively (see **Scheme 11**). This behaviour is consistent with a single-step concerted mechanism, analogous to the ground-state RDA process occurring in neutral molecules in the condensed phase. On the other hand, analogous dissociation is nonstereospecific in *endo*-, *exo*- and *trans*-2,3-diethoxycarbonyl-5,6-benzobicyclo[2.2.2]octanes 13, indicating involvement of a step-wise mechanism in this system (**Scheme 12**).

Retro-Diels–Alder (RDA) Fragmentation

The retro-Diels–Alder (RDA) fragmentation is highly stereospecific in a variety of bi-, tri-, tetra- and pentacyclic systems. Two examples are shown in **Scheme 13**. The diene radical cations are the most abundant species observed in the EI mass spectra of the *cis* isomers 14c and 15c, and practically absent in the *trans* counterparts 14t and 15t. The very high efficiency of this process in the *cis* isomers and the high stability of the molecular ions of the *trans* analogues suggest that the RDA dissociation of gas-phase ions takes place by a concerted mechanism, which exhibits symmetry conservation characteristics similar to those of the ground-state RDA process in neutral species.

Similar behaviour has been also observed using CI. Protonated dienes are formed only from *cis* isomers. Protonated dienophiles have been also observed in certain cases under CI, again only in *cis* isomers.

Scheme 10

Scheme 11

In contrast with the above behaviour, there have been reports on the occurrence of EI-induced RDA fragmentation in compounds with a *trans* junction of the cyclohexane and the adjacent rings (e.g. 16 and 17, **Scheme 14**). These results are indicative of a step-wise dissociation in these systems, in which the allylic bonds cleaved in the course of this process are either highly (as in 16) or lightly (as in 17) substituted. It has been proposed that the nonstereospecific step-wise behaviour of systems, such as 16, results from the low energy requirement for the cleavage of the fully substituted allylic 9–14 bond, which presumably is the initial step of the step-wise RDA dissociation. In systems such as 17, the low substitution pattern of the bonds cleaved in the course of the RDA process may result in a relatively high energy of

activation of the concerted pathway and in the consequent preference of the step-wise mechanism.

The partial stereospecificity of the RDA process in system 18 (**Scheme 15**) has been the subject of a thorough examination. Theoretical calculations and critical energy measurements led to the conclusion that the RDA fragmentation of both stereoisomers is a step-wise process involving a common distonic intermediate, but the energy barriers are different for the stereoisomers (**Scheme 15**).

Anchimeric Assistance

In many systems, variations in the abundances of certain fragment ions in the mass spectra of stereoisomers have

Scheme 12

been ascribed to anchimeric assistance. The loss of bromine from the molecular ions of stereoisomeric 1,2-dibromocyclopentanes and dibromocyclohexanes 19 (Scheme 16) is strongly affected by their configuration. The ion abundance ratio $[\text{M}-\text{Br}]^+/\text{M}^{*+}$ is higher for the *trans* isomer by a factor of 10 in the dibromocyclopentane and 42 in the dibromocyclohexane system at 70 eV, and the difference between the stereoisomers increases at lower ionization energies. A similar effect has also been observed in acyclic diastereoisomeric vicinal dibromoalkanes. Anchimeric assistance of one bromine atom in the expulsion of the other from the molecular ion is proposed as the explanation of the stereospecificity of this process (Scheme 16). This proposed mechanism finds support in the stereospecific behaviour of the two *trans*-1,2-dibromo-4-*t*-butylcyclohexanes (a)-20t and (e)-20t (Scheme 17). The stereoisomer (a)-20t, with the two axial Br atoms in the antiperiplanar conformation, gives rise to a much more abundant $[\text{M}-\text{Br}]^+$ ion than the diequatorial analogue (e)-20t.

The greater extent (by a factor of 2–10) of elimination of acetic acid from the MH^+ ions of *trans*-1,2- and 1,3-diacetoxycyclopentanes and -cyclohexanes upon $\text{CH}_4\text{-Cl}$ and isobutane-Cl, as compared with the *cis* isomers, has been also interpreted in terms of anchimeric assistance. The carbonylic oxygen of the nonprotonated acetoxy group in the *trans* isomers (e.g. 21t in Scheme 18) assists in the elimination of CH_3COOH , affording the stabilized cyclic fragmentation.

Numerous additional examples of a distinctive mass spectral behaviour of stereoisomers, which have been attributed to anchimeric assistance both under EI and CI

conditions, have been proposed in the literature. In some cases, particularly upon Cl, additional factors may be responsible for the distinctive behaviour. For instance, the higher abundance of the $[\text{MH}-\text{CH}_3\text{COOH}]^+$ ion in the CI mass spectra of the *trans*-diacetate 21t could also be attributed (at least in part) to the greater stability of the internally hydrogen bonded MH^+ ion of the *cis*-isomer.

Direct evidence for the operation of anchimeric assistance has been found in the CI behaviour of stereoisomeric 1,4-dialkoxycyclohexanes 22 (Scheme 19). The *trans*-diethers 22t afford very abundant $[\text{MH}-\text{ROH}]^+$ ions upon Cl in contrast to the corresponding *cis* counterparts, suggesting anchimeric assistance in the elimination of alcohol from the MH^+ ions of the *trans*-diethers. Collision-induced dissociation (CID) measurements of the $[\text{MH}-\text{ROH}]^+$ ions, obtained from various suitably deuterium labelled stereoisomeric 1-ethoxy-4-methoxycyclohexanes, indicated formation of symmetrical bicyclic ethyl and methyl oxonium ions by an anchimerically assisted alcohol elimination from the *trans*-diethers (the elimination of methanol is shown in Scheme 19). On the other hand, the CID measurements show that the *cis* isomers afford isomeric $[\text{MH}-\text{ROH}]^+$ ions, in which positions 2 and 3 (as well as 1 and 4, and 5 and 6) are not equivalent. These two results, namely the symmetrical structure and the high abundance of the $[\text{MH}-\text{ROH}]^+$ ions in the CI mass spectrum of the *trans*-diether 22t, in contrast to the non-symmetrical monocyclic structure and low abundance of these ions in the *cis* counterpart, are suggested as direct evidence for anchimeric assistance in the gas-phase ion dissociation process in that system. *Ab initio* calculations support the anchimerically assisted

**Scheme 13**

elimination observed in 22t. The energy difference between the anchimerically assisted and non-assisted elimination mechanisms in this system is not large ($\sim 2\text{--}3 \text{ kcal mol}^{-1}$).

Stereoelectronic Effects

One of the early reported cases of distinctive mass spectra of stereoisomers was the EI-induced behaviour of deacetylcyclindrocopol 23a and of its epimer at C-19, 23b (Scheme 20). The more pronounced loss of the hydrogen atom from position 19 of the molecular ion of

23b, as compared with that of 23a (10.6% versus 1.7%), was attributed to the antiperiplanar relationship of the 19-C–19-H bond and the p-orbital of the adjacent nitrogen atom in 23b, in contrast to the epimer 23a.

The pronounced different behaviour of the stereoisomeric bicyclic carbamates 24a and 24b (Scheme 21) also indicates the occurrence of a stereoelectronic effect. The *trans* isomer 24a, with the axial methoxycarbonylmethyl group, affords the much more abundant $[\text{M}-\text{CH}_2\text{COOCH}_3]^+$ ion possibly due to the stereoelectronic assistance of the π -orbital at the adjacent carbamate group. Similar stereoelectronic effects,

Scheme 14

Scheme 15

Scheme 16

resulting in distinctive bond dissociation processes of stereoisomers, have been observed in several other heterocyclic systems.

Ion-Molecule Reactions

Ion-molecule reactions, studied using the ion cyclotron resonance (ICR) technique, show considerable stereo-specificity in a number of systems, which enable distinction between stereoisomers. An early example of such a process is the gas-phase acetylation of *endo*- and *exo*-norborneol, shown in **Scheme 22**. The fourfold lower reactivity of the *endo*-isomer *endo*-25, as compared with the epimeric *exo*-25, is attributed to the steric hindrance in the approach of the bulky triacetyl cation to this stereoisomer.

Similar stereoselective behaviour has also been observed in the analogous gas-phase acetylation of *cis*- and *trans*-1-decalones and of the acetates of *cis*- and *trans*-4-*t*-butylcyclohexanols. The reaction is faster with the less hindered *trans* isomers in both cases.

Enantiomers: Chiral Recognition

Unimolecular fragmentation processes studied by MS are of achiral nature, and consequently insensitive to chirality differences. A key procedure for chiral recognition using MS is to add a chiral component to the process and detect the possibly different diastereoisomeric interactions under a variety of conditions (CI, FAB, electrospray ionization (ESI), Fourier transform ion cyclotron resonance (FTICR), CID).

The formation and dissociation behaviour of the gas-phase protonated dimers (or higher clusters) of dialkyl tartarates under CI conditions is one of the early and most widely studied examples of chiral recognition by mass spectrometry. The protonated dimer consisting of two enantiomeric molecules and that consisting of two molecules of the same enantiomer are diastereoisomeric species, and as such they may exhibit distinctive behaviour, usually of a quantitative nature. Isotope labelling of one of the enantiomers is necessary in order to observe the different behaviour of the two protonated dimers.

Chemical ionization using chiral reagent gases (e.g. 1-amino-2-propanol or 2-amino-1-propanol) has been shown to induce distinctive behaviour between enantiomers. Enantiomers could also be differentiated via S_N2 reactivity with chiral reagents in ion-molecule reactions. The resulting diastereoisomeric products were distinguished by tandem mass spectral techniques (MS/MS).

Scheme 21

Scheme 22

Host–guest interactions using chiral hosts have been relatively widely investigated under a variety of mass spectral conditions as tools for chiral recognition in numerous systems. The use of chiral matrices in secondary ion mass spectral measurements (FAB ionization) is a promising way for distinguishing between enantiomers.

Conformational Studies of Biopolymers

Electrospray ionization (ESI) has become a powerful method for the investigation of thermally labile polar biopolymers. The attachment of a large number of protons to the basic sites of proteins in the course of the ESI experiment affords a spectrum of multiply charged ions in the gas phase, which allows mass analysis using mass spectrometers with relatively low mass-to-charge ranges. With the steadily increasing use of this technique it has become apparent that more information may be obtained from the results of ESI analysis than just the molecular weight of the protein.

Careful measurements of ESI mass spectra of proteins show that changes in the solvent or in the pH of the examined solution may have an effect on the charge-state distributions. These different distributions have been interpreted as being the result of differences in the

conformation of the proteins in the examined solutions. For example, ESI spectra of lysozyme, obtained from a 100% aqueous solution at pH 5.0 and from a solution containing 50% acetonitrile and 1% formic acid, show charge state maxima at 9+ and 12+, respectively. These different charge-state distributions are interpreted in terms of the degree of folding of the proteins in the original solutions. The protein molecules are unfolded to a greater extent in the organic than in the aqueous solution.

The unfolding of the molecules exposes sites of protonation which were buried in the folded native conformation, resulting in the higher charge states in the ESI mass spectrum obtained from the 50% acetonitrile–1% formic acid solution.

Hydrogen/deuterium exchange measurements with the aid of ESI mass spectrometry have also been used successfully to explore conformational changes of proteins in solution. Elements of secondary structure that involve internal hydrogen bonding in the core of the protein are protected against hydrogen exchange, whereas regions exposed to the solvent undergo hydrogen exchange more readily.

J	coupling constant
k_r	rate coefficient
q_{zz}	largest component of electric field gradient
Q	quadrupole moment
r	distance between nuclei
R	ratio of resonance frequencies
T_1	spin–lattice relaxation time
T_2	spin–spin relaxation time
$T_{1\rho}$	rotating frame relaxation time
W_Q	line width
δ_{ii}	component of chemical shift
δ_{iso}	isotropic chemical shift
$\Delta\delta$	chemical shift anisotropy
ν	resonance frequency
η	asymmetry parameter
Ξ	resonance frequency in a magnetic field strength that gives the ^1H resonance of SiMe_4 at exactly 100 MHz

A very wide range of experiments is available to the NMR spectroscopist for inorganic structural analysis. The full armoury of single- and multi-dimensional NMR techniques used for the structural analysis of organic compounds may be used for inorganic systems, with the added dimension of the multinuclear approach. X-ray structural analysis of crystalline compounds has long been fundamental to inorganic structure determination and it is now clear that solid-state NMR, particularly with the magic angle spinning (MAS) technique, is capable of providing complementary data making the synergistic combination of X-ray and MAS-NMR methods very powerful indeed. In reviewing applications of NMR methods to inorganics, it is important to consider the insight that NMR provides into dynamic aspects of the molecular structures; intermolecular exchange processes in solution, and intramolecular fluxionality in both solution and solid state can be delineated, and very often thermodynamic and kinetic parameters derived which can be interpreted in

mechanistic terms. It is often the case, particularly for transition metal compounds, that the molecule is paramagnetic. While the unpaired electron(s) can cause undesirable effects on the NMR spectra, e.g. excessive broadening of resonances, it may often be the case that the paramagnetic *shift* at ligand resonances may be useful in resolving erstwhile overlapping signals, or in providing information on the distribution of unpaired spin density throughout the molecule. In addition to the intrinsic information from such paramagnetic molecules, the addition of a paramagnetic compound (e.g. a lanthanide chelate) to a solution of a diamagnetic compound can induce paramagnetic shifts and changes in line widths in resonances of the latter compound (shift and relaxation agents). These changes can be valuable in providing structural information or in enhancing contrast in magnetic resonance images.

The Multinuclear Approach

In any structural problem, the first step is to decide which NMR experiments will provide the most definitive information in the shortest time. Usually, although not exclusively, solution-state spectra are measured, and if the inorganic compound includes an organic ligand, then ^1H and ^{13}C spectra are essential. The choice of additional spectra from other nuclei must be directed using the same criteria – information content and economy of time. In this it is necessary to know the inherent sensitivity of the isotope, and the value of its spin quantum number (I). Isotopes with $I = 1/2$ generally give rise to narrower resonances ('high-resolution' nuclei), whereas those with $I > 1/2$ often yield much broader resonances (quadrupolar nuclei) and spectral information (chemical shifts and scalar couplings) may be obscured. Some NMR-active isotopes of potential interest to the inorganic chemist are listed in **Table 1**, and this list is by no means exhaustive since there are considerably more than 100 NMR-active stable isotopes across the periodic table.

Careful consideration should be given to the ease of observation of the NMR spectrum of a given isotope. Generally, the ease of observation will increase with increase in the magnetic field strength of the spectrometer, but it is possible that at the higher end of the available

magnetic field strength range (≥ 14 T), the resonances of certain nuclei, particularly the heavier metals such as platinum, mercury or lead, may become broadened by the influence of chemical shift anisotropy (see below), thereby abrogating the beneficial effects of the higher field. Another consideration is the combination of low natural abundance and small nuclear magnetic moment (low resonance frequency) giving a low intrinsic receptivity, as for ⁵⁷Fe. In such cases the situation may be partially alleviated by resorting to isotopic enrichment, as illustrated in **Figure 1**, which shows two ⁵⁷Fe resonances from a 20 mM solution of the superstructured haem model compound ⁵⁷Fe^{II}PocPiv(1,2-diMeIm) (CO) (94.5% enriched in ⁵⁷Fe). Even at this high level of enrichment and high magnetic field, the spectrum still required about 20 h of instrument time for the spectral accumulation. The spectrum does illustrate the extreme sensitivity of the ⁵⁷Fe chemical shift to fairly remote structural effects since the two ⁵⁷Fe resonances are believed to arise from the presence of the two atropisomers (α and β) due to restricted rotation of the pivaloylamido picket. In considering NMR spectra of the quadrupolar nuclei, in addition to the question of sensitivity, there is the question of resolution of chemical shifts, since chemical shift differences within a spectrum may be

obscured by relatively large line widths (W_Q) exhibited by the resonances due to quadrupolar relaxation. As a very rough guide to the line width problem, the line width may increase with the square of the quadrupole moment, hence less broadening is expected in spectra of ²H or ⁶Li:

$$W_Q \propto \left(\frac{e^2 q_{zz} Q}{b} \right)^2 \left(1 + \frac{1}{3} \eta^2 \right) \quad [1]$$

where e is the electronic charge, b Planck's constant, q_{zz} the largest component of the electric field gradient and η the asymmetry parameter for q . However, since the electric field gradient at the nucleus, caused by the surrounding electron distribution, is also important, this may counter the effect of a larger quadrupole moment as for the ⁵¹V spectrum of the product of partial hydrolysis of VO(NO₃)₃ (**Figure 2**, which also includes the ¹⁷O spectrum). ¹⁷O enrichment can often be achieved starting with the relatively inexpensive source H₂¹⁷O, and the relatively narrow lines often exhibited by ¹⁷O resonances can provide a wealth of structural data as shown in **Figure 3** for the aqueous isopolytungstate solution (enriched to 5% ¹⁷O), where the ¹⁷O chemical shifts are sensitive to a variety of structural features, particularly the metal–oxygen bond lengths.

Figure 1 19.58 MHz ^{57}Fe NMR spectrum of the $^{57}\text{Fe}^{\text{II}}$ PocPiv(1,2-diMelm)(CO) adduct in CD_2Cl_2 solution at 298 K. Reproduced with permission from Gerothanassis IP, Kalodimos CG, Hawkes GE, and Haycock PR (1998) *Journal of Magnetic Resonance* 131: 163–165.

The NMR Parameters

Chemical Shifts

For samples of inorganic molecules in solution, each chemically distinct site for an atom in the molecule will result in a distinct *isotropic* chemical shift for its nucleus in the NMR spectrum. What is important from the structural point of view is that these chemical shifts are resolved in the spectrum, and this in turn will be determined by the sensitivity of the chemical shift to structural changes. Some nuclei are more sensitive than others, and this is usually represented by the reported chemical shift range of the nucleus. ^1H chemical shifts in inorganic compounds typically span a range ~ 20 ppm, whereas heavier isotopes often exhibit much greater chemical shift ranges, e.g. hundreds of ppm for ^{17}O , ^{19}F , ^{29}Si and ^{31}P , and this may run to thousands of ppm for heavy metals such as ^{195}Pt or ^{199}Hg . Each isotropic chemical shift is in fact an average of three principal chemical shift values.

Figure 2 NMR spectra at 294 K of the $\text{VO}(\text{NO}_3)_3 - \text{H}_2\text{O}$ (mole ratio 1:0.3) system in MeNO_2 : (a) 105.1 MHz ^{51}V spectrum and (b) 54.2 MHz ^{17}O spectrum. Reproduced with permission from Hibbert RC, Logan N, and Howarth AW (1986) *Journal of the Chemical Society, Dalton Transactions* 369–372.

The chemical shift is determined by the interaction of the electron distribution with the spectrometer magnetic field; hence a nucleus in an asymmetric electronic environment (the general case) will experience a change in chemical shift with the orientation of the molecule in the magnetic field. The chemical shift is thus represented as a second-rank tensor (3×3 values) and it is possible to find a molecule-fixed Cartesian coordinate system which diagonalizes this tensor to give the three principal components (δ_{11} , δ_{22} , δ_{33}). In any solution sample the molecules undergo rapid random motion, including rotation, and as a result these components average to a single isotropic chemical shift (δ_{iso}):

$$\delta_{\text{iso}} = (\delta_{11} + \delta_{22} + \delta_{33})/3 \quad [2]$$

Although it is not possible to obtain values for the independent components from solution-state spectra, it is possible in certain cases to obtain some information such as the chemical shift anisotropy $\Delta\delta$ (see below):

$$\Delta\delta = \delta_{33} - (\delta_{11} + \delta_{22})/2 \quad [3]$$

where δ_{33} is the component furthest removed from the average δ_{iso} .

MAS-NMR spectra of the solid state can provide values for the components δ_{ii} as shown in **Figure 4**. The *static* spectrum (**Figure 4a**) of the powder sample is the superposition of different chemical shifts resulting from all possible orientations of the molecules in the discrete particles of the sample, and the components δ_{ii} are as indicated. Usually such broad lines would mask any resolution of distinct chemical shifts. The MAS spectra

Figure 3 54.2 MHz ^{17}O NMR spectrum of isopolytungstate at 353 K, pH 1.1. Species: a, $\alpha\text{-}[\text{H}_2\text{W}_{12}\text{O}_{40}]^{6-}$, metatungstate; b, $\alpha\text{-}[\text{HW}_{12}\text{O}_{40}]^{7-}$; c, ψ' -metatungstate; probably $\beta\text{-}[\text{HW}_{12}\text{O}_{40}]^{7-}$. (Figures 4b–d) consist of a centre-band resonance at the isotropic chemical shift (δ_{iso}) and side bands spaced at the rotation frequency, and offer two advantages over static spectra. The first advantage is that within the centre band there may be chemical shift resolution (in this case there is only one ^{31}P environment and therefore only one isotropic chemical shift) and the second is that the total integrated intensity of the spectrum is within the relatively sharp lines and so the sensitivity of the observation is greatly enhanced in comparison with that of the static spectrum. The intensity pattern of the spinning side bands roughly follows the static spectrum, and these intensities can be used to obtain values for the components δ_{ii} . To illustrate the utility of such measurements, it has been shown that the ^{31}P isotropic shifts and chemical shift tensor components (δ_{ii}) from a series of phosphido-bridged iron complexes $\text{Fe}_2(\text{CO})_6(\mu\text{-X})(\mu\text{-PPh}_2)$ gave an excellent correlation with the crystallographically determined Fe–P–Fe bond angles. In a related study on iron complexes with asymmetrical bridging carbonyl ligands $\text{Fe}\cdots\text{CO}\text{--}\text{Fe}$ the ^{13}C chemical shift anisotropy and the component δ_{33} (associated with the C–O bond axis) both correlated with the difference in the two Fe–C distances. The isotropic ^{13}C chemical shift is not a reliable indicator of the metal–carbonyl group bonding, and typically cannot be used to distinguish unequivocally between terminal and bridging carbonyl groups (e.g. M–CO vs

M–CO–M). However, as shown in Table 2, the chemical shift anisotropy values are distinctive of the carbonyl group bonding.

Coupling Constants

The two important parameters to consider are the internuclear scalar couplings and the internuclear dipolar couplings. Scalar or spin–spin coupling constants are observed in both solution- and solid-state spectra and are usually considered to be transmitted via bonding electrons. The magnitude of the scalar couplings varies dramatically with the isotopes concerned, the nature and number of intervening bonds, coordination number, oxidation state, etc. Interproton couplings are typically small (<20 Hz) but couplings between heavier isotopes may be fairly large, up to about 10 000 Hz, for example, for the one-bond $^{31}\text{P}\text{--}^{199}\text{Hg}$ coupling in Ph_3PHgX_2 , X = OCOCH_3 or OCOCF_3 . The splitting patterns induced by the scalar couplings are used to determine the number of interacting nuclei and the magnitudes of the couplings may be interpreted in terms of bonding and conformation. Internuclear dipolar couplings are direct through space interactions between magnetic nuclei and values may be as large as 50 000 Hz between protons, being dependent upon the inverse third power of the separation (r^{-3}). The splitting caused by this effect is

Figure 4 119.05 MHz solid-state ^{31}P NMR spectrum of diethyl phosphate spinning at the magic angle. ν_{ROT} indicates the spinning frequency. Reproduced with permission from Herzfeld J and Berger AE (1980) *Journal of Chemical Physics* 73: 6021–6030.

dependent on the orientation of the internuclear vector relative to the spectrometer magnetic field and for molecules in solution undergoing rapid molecular tumbling the effect averages to zero. Therefore, in solution spectra

there is no obvious direct effect on one-dimensional spectra due to dipolar couplings. However, they are responsible for indirect effects, such as nuclear relaxation and the nuclear Overhauser effect (see below). In solid-state NMR, dipolar interactions provide one mechanism for line broadening, particularly with hydrogen present in the molecule. MAS (e.g. using 4 mm o.d. rotors at 15 kHz) is used to reduce the dipolar interactions and for the observation of nuclei other than hydrogen this is often used in conjunction with high-power ^1H decoupling. For observation of solid-state ^1H spectra it is often necessary to use the combination of MAS with a suitable pulse sequence (CRAMPS; combined rotation and multiple pulse spectroscopy). If the dipolar interactions are relatively weak then MAS alone may be sufficient to allow resolution of chemical shifts, as shown in **Figure 5** for some metallo-hydride complexes. While much attention has been focused on methods for reducing or eliminating the effects of the dipolar interactions in solid-state NMR, the presence of the dipolar interaction could be useful in showing the spatial proximity of atoms in a structure. Several multiple-pulse two-dimensional experiments have been proposed, including trains of pulses, synchronized in time with the MAS rotation period. These sequences refocus the dipolar interaction, as illustrated in **Figure 6** for the ^{31}P double-quantum–single-quantum correlation spectrum of a polycrystalline powder sample of $\text{Cd}_3(\text{PO}_4)_2$. There are six crystallographically distinct phosphorus sites in the structure and six resolved ^{31}P resonances in the one-dimensional spectrum. The contours link pairs of phosphorus sites which have a measurable dipolar interaction (are in spatial proximity) and the more intense correlations indicate greater proximity in the structure.

Relaxation Times

The principal relaxation times measurable for resolved resonances from solution state samples are the spin-lattice relaxation time (T_1) and the spin-spin relaxation time (T_2). Spin echo methods may be used to measure T_2 values and these are often useful in defining chemical exchange rate processes. T_1 values are readily obtained from the inversion–recovery experiment and

Figure 5 300 MHz solid-state ^1H MAS-NMR spectra: (a) $\text{H}_2\text{Os}_3(\text{CO})_{10}$, MAS rate 8.1 kHz; (b) $\text{H}_2\text{FeRu}_3(\text{CO})_{13}$, MAS rate 9.5 kHz. can be directly used to provide structural information. For nuclei with spin $I = 1/2$ in diamagnetic molecules in solution there are two principal mechanisms which contribute to the rate of the relaxation (T_1^{-1}), namely the dipole–dipole interaction and the chemical shift anisotropy mechanism. The dipole–dipole interaction occurs between magnetic nuclei which are in close spatial proximity in the molecule and if the population distribution of nuclei across the energy levels of one site is disturbed away from its equilibrium value (usually the populations are equalized by a second radiofrequency field) then this is reflected as a change in the intensity of the resonance from the other site. This is the so-called nuclear Overhauser effect (NOE) and is widely used as a structural tool; particularly the interproton NOE is used in a qualitative or quantitative manner to estimate distances between protons in biomolecules, and thereby serves to define conformation. Such interproton NOEs will similarly be useful for determination of structure in organometallic species, and in addition the structural inorganic chemist will be able to utilize the homonuclear

Figure 6 202.5 MHz solid-state ^{31}P MAS-NMR spectrum of $\text{Cd}_3(\text{PO}_4)_2$. The two-dimensional spectrum shows the single-quantum–double-quantum dipolar correlations. Reproduced with permission from Dollase WA, Fecke M, Förster H, et al. (1997) *Journal of the American Chemical Society* 119: 3807–3810.

NOE between other nuclei which are present at a high level of abundance, for example the ^{31}P – ^{31}P NOE might be particularly useful. The heteronuclear NOE might also be expected to provide useful conformational information where sensitivity permits, and ^{13}C – ^1H and ^{31}P – ^1H are obvious candidates, and ^6Li – ^1H has also been used. The relaxation rate of a nucleus due to its dipole–dipole interaction (T_1^{-1}) with a neighbouring nucleus at a distance r is proportional to r^{-6} . This distance dependence has been put to a number of uses, in particular in structural studies of molecular hydrogen complexes. If hydrogen is bound as two distinct M–H groups then the separation between the hydrogens will be greater than if the hydrogen is bound as molecular hydrogen $\text{M}(\text{H}_2)$. Therefore, for the molecular hydrogen case the hydrogens will experience a stronger mutual dipole–dipole interaction and the rate of spin–lattice relaxation will be greater. Ideally the experiment should be calibrated by measuring the relaxation rate for a pair of nuclei at a known separation in the same molecule, perhaps for nuclei in an organic ligand.

The rate of nuclear spin–lattice relaxation due to the chemical shift anisotropy mechanism ($T_1^{\text{CSA}})^{-1}$ depends upon the magnitude of the chemical shift anisotropy ($\Delta\delta$) and the strength of the spectrometer magnetic field (B_0) squared. This dependence of the rate on B_0^2 provides a means of estimating a value for $\Delta\delta$ if the mechanism is important (significant value for $\Delta\delta$) and if the

measurement of the rate of relaxation can be made at several different field strengths (B_0). This may be applied to ^{13}C relaxation for the carbonyl groups of organometallic complexes (see Table 2). A related study on metal carbonyl complexes made use of the quadrupolar relaxation rate shown by those nuclei with spin $I > 1/2$, here ^{17}O with $I = 5/2$. The relaxation rate of such quadrupolar nuclei is dominated by the contribution, $(T_1^Q)^{-1}$, from the quadrupolar mechanism, and in favourable cases it is possible to determine the quadrupole coupling constant (QCC; cf. eqn [1]). Table 3 shows values for the ^{17}O QCC for the carbonyl groups of some metallo-carbonyl complexes, and again the derived parameter is seen to be diagnostic of the type of carbonyl group.

Dynamic Processes

NMR spectroscopy is a most powerful method for the investigation of dynamic processes occurring at the molecular level. In particular, both intramolecular and intermolecular chemical exchange processes in solution may be investigated and for inorganic compounds these processes include ligand exchange, conformational changes, rearrangements and fluxional processes. There are various NMR parameters which may be used to monitor the dynamic process, and the particular set of NMR experiments to be used may depend in part on the order of magnitude for the rate coefficient of the process. The rate process may be termed either 'slow' or 'fast', but these labels really depend on the NMR parameter being used to monitor the process. For many years the most common method to study rate processes both qualitatively and quantitatively has been the band shape method. Here the NMR parameters may be chemical shifts (measured in frequency units) and/or coupling constants. For a two-site exchange process $A \leftrightarrow X$ the spectrum will be affected when the rate is within the limits

$$T_2 \geq k_r^{-1} \geq \left(\frac{1}{2}\pi^2\Delta\nu^2T_2\right)^{-1} \quad [4]$$

where $\Delta\nu$ is the difference in resonance frequency (between sites A and X) or the coupling constant being

averaged. Exchange processes in the fast exchange limit ($k_r \geq 10^4 \text{ Hz}$) may contribute to the rotating frame relaxation time ($T_{1\rho}$), and measurement of $T_{1\rho}$ as a function of the strength of the spin-lock field can give a value for the rate coefficient. More recently, magnetization transfer experiments, both one- and two-dimensional, have been used to explore multi-site slow exchange situations. In these experiments the population distribution between the nuclear energy levels for one or more of the sites is disturbed from the equilibrium. This can be by equalization of the populations (cf. saturation as described above for the NOE) or by inversion of the populations by a selective 180° radiofrequency pulse for the 1D experiment or a non-selective pulse for the 2D experiment (known as EXSY). The chemical exchange can then transmit the disturbance throughout the exchanging system. However, since spin-lattice relaxation is always occurring in order to restore the equilibrium nuclear distribution, then this method is applicable when the rate coefficient $k_r \geq T_1^{-1}$. In the two-dimensional experiment, which is exactly the same as the 2D NOESY experiment, the advantage is that it is possible to obtain a very clear picture of the magnetization transfer pathways in addition to being able to quantify the rate coefficients. This is illustrated in Figure 7, where the off-diagonal contours link chemical shifts of pairs of slowly exchanging methyl groups among the six distinct methyls of the 2,4,6-tris(3,5-dimethylpyrazol-1-yl)pyrimidine (tdmpzp) ligands.

Figure 7 Methyl region of the 400 MHz ^1H two-dimensional EXSY NMR spectrum of $[\text{ReBr}(\text{CO})_3(\text{tdmpzp})]$ in $\text{CDCl}_2/\text{CDCl}_2$ solution at 296 K. Sensitivity Enhancement by Polarization Transfer

One-Dimensional Experiments

The solution-state polarization transfer experiments described here all depend upon the existence of a resolved scalar coupling between a sensitive nucleus (e.g. ^1H , ^{31}P) and an insensitive nucleus (e.g. ^{57}Fe , ^{109}Ag). The one-dimensional experiments are based upon the so-called INEPT or DEPT pulse sequences and involve the initial creation of anti-phase magnetization for the more sensitive nucleus; this is effectively the selective inversion (of populations) for part of the multiplet of the sensitive nucleus. This has the effect of enhancing the population differences across the energy levels of the coupled, less sensitive nucleus, thus making the observed resonances more intense. Polarization (population differences) has thus been transferred from the more sensitive to the less sensitive nucleus. For a single acquisition the sensitivity improvement for spin $I = 1/2$ nuclei is of the order of the ratio of the resonance frequencies; hence using the ^{31}P polarization to drive the ^{109}Ag populations results in a sensitivity enhancement factor ~ 8.6 compared with 'single pulse' observation of the ^{109}Ag spectrum. There is a second benefit to using the polarization transfer sequences in that typically the spectrum must be accumulated over a period of time and each individual acquisition sequence should be separated by a 'relaxation delay'. The intensity of the observed resonance is derived from the nonequilibrium populations of the more sensitive nucleus, and it is often the case that relaxation times for ^1H and ^{31}P are shorter than for the metal nuclei, and therefore the accumulation sequence with polarization transfer can be repeated with greater frequency than the 'single pulse' observation. An example of the sensitivity enhancement is shown in **Figure 8** where the $^{109}\text{Ag}\{-^{31}\text{P}\}$ INEPT experiment provides considerably improved signal/noise ratio over the normal acquisition, with about one sixth of the number of scans accumulated with INEPT. There is one disadvantage common to all 1D and 2D polarization transfer experiments and this is the need to have prior knowledge of the magnitude of the scalar coupling constant (J , Hz) since there are delays in the various pulse sequences which are related to J . It is often possible to obtain a value for the coupling constant from the ^1H (or ^{31}P) spectrum, but in other cases a guess must be made for J , and the experiment possibly repeated for a range of assumed J values.

Two-Dimensional Experiments

Two-dimensional experiments provide heteronuclear shift correlations with the spectrum detected at the frequency of the more sensitive nucleus, and involve a double polarization transfer from sensitive to less

Figure 8 13.97 MHz ^{109}Ag NMR spectra of $[\text{Ag}(\text{dppe})_2]\text{NO}_3$ in CDCl_3 solution at 300 K: (a) single pulse acquisition (accumulation of 12 111 scans); (b) $^{109}\text{Ag}\{-^{31}\text{P}\}$ INEPT experiment (accumulation of 2048 scans). sensitive to sensitive nucleus. The sensitivity improvement over the direct 'single pulse' observation of the less sensitive nucleus is even more dramatic than for the one-dimensional methods; here it is $\sim R^{5/2}$, where R is the ratio of the resonance frequencies, and for the $^{31}\text{P}\text{--}^{109}\text{Ag}$ example used above the sensitivity improvement is ~ 218 . These experiments are often used to facilitate the observation of the spectrum of the less sensitive nucleus. Several experiments may be used and, when the one bond coupling is known the choice is between HMQC (heteronuclear multiple quantum coherence) and HSQC (heteronuclear single quantum coherence). There are advantages and disadvantages to both experiments; for example, the HMQC pulse sequence has fewer pulses than the HSQC, making the former experiment less susceptible to instrumental imperfections. However the resulting HMQC two-dimensional plot includes homonuclear coupling for the more sensitive nucleus (e.g. ^1H or ^{31}P), reducing the intensities of the correlation peaks, and the line widths are determined by the relaxation rate of the multiple quantum coherence which may be faster than that of the single quantum coherence leading to

Figure 9 A ^{109}Ag – ^{31}P HSQC correlation experiment with inverse (^{31}P) detection (^{109}Ag at 23.3 MHz, ^{31}P at 202 MHz) of a silver–chiral ferrocene complex in the presence of an excess of the isonitrile $\text{CNCH}_2(\text{CO}_2\text{Me})$. broader lines in the HMQC plot. An example is the ^{109}Ag – ^{31}P correlation shown in Figure 9.

Paramagnetic Systems

The incidence of paramagnetism in inorganic molecules and materials is fairly common, and is due to the presence of unpaired electrons, usually associated with a metal centre. This paramagnetism will often lead to large chemical shifts of the NMR-active nuclei in the sample and may also induce severe line broadening of the resonances. Certainly paramagnetic metal centres in a variety of biomolecules may result in spectra dispersed on the chemical shift scale over hundreds of ppm, compared with tens of ppm for diamagnetic analogues. Such effects are fairly common, for example, in the ^1H and ^{13}C NMR spectra of a wide range of natural haem systems containing iron, and in model haem and porphyrin systems

wherein the paramagnetic shifts may be related, in part, to the distribution of unpaired electron spin density throughout the molecule. The paramagnetism of inorganic complexes may be used to good effect in other areas. Lanthanide metals complexed with a range of organic ligands have been used for a number of years as shift or relaxation reagents. The shift (relaxation) reagent, when added to a solution of a diamagnetic compound, may form a weak complex with the diamagnetic molecule and result in paramagnetic changes in the chemical shifts (relaxation rates) of the nuclei in the substrate. The magnitudes of these changes in shift or relaxation rate depend upon the geometry of the weak complex and so may be analysed to give information about the structure of the diamagnetic compound. A second area of application of paramagnetic organometallic complexes is as contrast agents for use in MRI experiments. When the complex is introduced *in vivo*, if there is a differential distribution of the agent between normal tissue and a lesion, then the agent will induce a differential in the relaxation rates of the water protons in these regions. Since the contrast in the MR image can be tuned to the relaxation properties of the water protons, then enhanced contrast in the image is obtained.

Structural Chemistry Using NMR Spectroscopy, Organic Molecules

Nuclear magnetic resonance spectroscopy is one of the most powerful tools that chemists use to determine the structure of compounds. Generally, NMR spectroscopy is the technique that most chemists, especially organic chemists, use first and routinely in structural analysis. In organic compounds, this non-destructive spectroscopic analysis can reveal the number of carbon and proton atoms and their connectivities, the conformations of the molecules, as well as relative and absolute stereochemistries, for example. The advent of pulsed field gradient (PFG) technology for NMR spectrometers has allowed the routine acquisition of sophisticated one-dimensional (1D) and two-dimensional (2D) NMR spectra in relatively short periods of time on complex organic molecules. This in turn has revolutionized organic structure determination such that deducing the three-dimensional structure of compounds takes a fraction of the time it used to. Mention of relevant 2D experiments that can aid in structure determination will be made in the appropriate sections herein.

This article is geared toward the analyses of small organic compounds, and will cover the following topics: practical tips in sample preparation; basic principles of one-dimensional ^1H and ^{13}C NMR spectroscopy and their use in organic structure determination, including chemical shifts, coupling constants and stereochemical analyses; and the application of more sophisticated 1D and 2D experiments to structure elucidation. Examples of structural analyses of organic compounds via NMR methods are ubiquitous in the literature such that it is impractical to mention more than just a few of them here. Therefore, the reader is encouraged to peruse the organic chemistry literature to find structural analyses of the specific types of organic compounds of interest. This article will deal mainly with generalities of organic compound structure elucidation, although several relevant examples will be presented.

General Practical Considerations

Deuterated solvents are utilized with FT NMR spectrometers to provide an internal lock signal to compensate for drift in the magnetic field during the experiment. The more common solvents used for organic compounds are CDCl_3 , CD_3CN , CD_3OD , acetone- d_6 , benzene- d_6 ,

DMSO- d_6 and D_2O . Since all deuterated solvents contain some protonated impurities (e.g. CHCl_3 in CDCl_3), one should choose a solvent that will not interfere with the NMR peaks of interest from the sample. Tetramethylsilane (TMS) is usually added to the sample as an internal standard for both proton and carbon spectra, being set at 0.0 ppm in both cases. However, the small protonated solvent impurities also make good standards as the chemical shifts of these peaks are published in many texts and are reported relative to TMS.

Protons provide the highest sensitivity for NMR observations, and therefore only small quantities of sample are needed (1–10 mg in 0.5 mL of solvent for an FT instrument). ^{13}C NMR has a much lower sensitivity than proton NMR due to the low natural abundance of ^{13}C (1.1%) compared with ^1H (close to 100%), and the fact that the energy splitting and hence the resonance frequency for carbon is approximately one quarter that of proton. Thus, for a spectrometer whose ^1H frequency is 300 MHz, the frequency for ^{13}C is 75.5 MHz. To obtain a carbon NMR spectrum in a timely manner, one needs to use either more sample than for a ^1H NMR spectrum (>20 mg of a compound with $\text{MW} \approx 150\text{--}300 \text{ g mol}^{-1}$), or a higher field spectrometer.

^1H NMR

As mentioned earlier, ^1H NMR is a very valuable method for obtaining information regarding the molecular structure of organic compounds with any number of protons. The electronic environment, as well as near neighbours and stereochemistry, can be determined by analysing the chemical shifts and spin–spin couplings of protons. The relative number of protons can be determined by direct integration of the areas under the peaks (multiplets), as the number of protons is directly proportional to the area under the peaks produced by those protons. To obtain accurate integrations, however, the relaxation delay needs to be at least 5 times the longest T_1 in the sample.

Proton Chemical Shift

Chemical shifts are diagnostic of the electronic environment around the nucleus in question. Withdrawal of electron density from around the nucleus will deshield the nucleus, causing it to resonate at a lower field (higher

frequency or chemical shift). Higher electron density around a nucleus results in shielding of the nucleus and resonance at higher field (lower frequency or chemical shift (δ)). Therefore, basic details of the molecular structure can be gleaned from analysis of the chemical shifts of the nuclei. Factors that affect the electron density around the proton in question include the amount of substitution on the carbon (i.e. methyl, methylene, methine), the inductive effect of nearby electronegative or electropositive groups, hybridization, conjugation interactions through π bonds, and anisotropic (ring current) effects. Tables of proton chemical shifts can be found in various texts, such as those listed in Further Reading.

As alkyl substitution increases on the carbon that possesses the proton(s) in question, the deshielding increases due to the higher electronegativity of carbon compared with hydrogen (e.g. $\text{CHR}_3 > \text{CH}_2\text{R}_2 > \text{CH}_3\text{R}$), producing a downfield shift of the resonances (methine most downfield, methyl most upfield). The deshielding effect of electron-withdrawing groups depends directly upon the electronegativity of these groups, and upon whether their effects are inductive (less effective) or through resonance (more effective). This deshielding effect falls off rapidly with increasing number of bonds between the observed proton and the electronegative group. One can, therefore, estimate chemical shifts of alkyl protons by analysing the amount of carbon substitution and the effects of nearby electron-withdrawing groups. A fairly accurate calculation of chemical shifts for methylene protons attached to two functional groups ($\text{X}-\text{CH}_2-\text{Y}$) is possible by using Shooley's rule, where the shielding constants for the substituents, Δ_i , are added to the chemical shift for methane. Tables of these shielding constants can be found in most texts on NMR spectroscopy.

To some extent, hybridization also influences the electron density around the proton in question by electronegativity effects. With increasing s character in a C-H bond, the electrons are held closer to the carbon nucleus. The protons consequently experience less electron density and are, therefore, more deshielded. This reasoning applies very well to protons attached to sp^3 rather than sp^2 carbons. For sp (acetylenic) protons, however, anisotropic effects are the dominating factors.

Electron-donating or electron-withdrawing groups directly attached to aromatic or alkene sp^2 carbons greatly affect the chemical shifts of aromatic or vinyl protons via π bond interactions (resonance). Thus, vinyl protons on the β -carbon of an α,β -unsaturated carbonyl system are further downfield (more deshielded) than the proton on the α -carbon due to resonance, and the opposite holds true for the β -proton(s) of a vinyl ether, as shown in **Figure 1**. In aromatic systems, electron-withdrawing

Figure 1 Shielding and deshielding effects due to resonance.

Figure 2 Proton H_a is deshielded by ~ 1 ppm due to the ring current of the nearby phenyl group.

groups deshield the protons ortho and para to it relative to unsubstituted benzene, while a group that is electron-donating by resonance will shield the ortho and para protons such that they resonate at a field higher than unsubstituted benzene ($\delta 7.27$). Empirical methods for estimating the chemical shifts of protons on substituted alkenes and benzene rings have been developed (see Further Reading). It should be realized, however, that the anisotropies of aromatic and alkenyl systems are also responsible for the larger than expected downfield shifts of the protons. The large downfield shift of aldehyde protons ($\sim \delta 9.5$) is due in large part to the anisotropic shielding/deshielding effect (called the cone of shielding/deshielding in carbonyls), as seen in alkenes and aromatic compounds.

Shielding and deshielding effects via anisotropy caused by ring currents can also affect protons not directly attached to the alkene, alkyne, carbonyl or aromatic systems. A good example of this is shown in **Figure 2**. The calculated chemical shift of the methine proton H_a in the absence of any ring current effects is $\delta 4.40$, while the observed chemical shift is $\delta 5.44$. The low energy conformation of the molecule (from molecular modelling) has one of the phenyl rings very near the proton H_a .

Therefore, it appears that the ring current of this phenyl group is deshielding this proton by ~ 1 ppm.

In organic molecules possessing protons with very similar chemical shifts, such as steroids or carbohydrates, it would be advantageous to be able to simplify the spectrum by eliminating all spin–spin splittings, thereby allowing the determination of resonance frequencies by only chemical shift effects. An improved method has been developed to produce this type of ‘chemical-shift spectrum’, and is illustrated in **Figure 3**. Overlapping resonances are resolved into singlets, and this allows for a more straightforward structural assignment of the resonances. Near neighbours, coupling constants and relative stereochemistries can be determined by other spectral editing techniques and experiments (see below).

Through-Bond Coupling: Determination of Near Neighbours and Stereochemistry

The analysis of through-bond spin–spin coupling (scalar or J coupling) allows for ready determination of the number of neighbouring protons, as well as the relative stereochemistry in certain cases. See the texts listed in Further Reading for more in-depth discussions of spin–spin coupling. In short, spin–spin couplings occur between magnetically nonequivalent nuclei (here, protons) through intervening bonding electrons, and decrease with increasing number of intervening bonds. Protons that are chemically equivalent (interchangeable by a symmetry operation) are magnetically equivalent if

they exhibit identical coupling to any other nucleus not in that set. However, protons with the same chemical shift do not split each other even when the coupling constant between them is non-zero. Rapid rotation about a C–C single bond, such as with a CH_3 group, results in an average environment for each methyl proton, and hence, equivalence.

Interacting protons with very different chemical shifts are weakly coupled if the difference in chemical shifts between the coupled protons, $\Delta\delta$, is large compared to the coupling constant J , i.e. $\Delta\delta/J > 10$. The multiplets resulting from this weak coupling are considered ‘first-order’ patterns, and can be interpreted easily. The multiplicity is governed by the $(2nI + 1)$ rule, where n is the number of *magnetically equivalent* coupled protons and I is the spin of the nucleus. In first-order systems, the multiplicities and peak intensities of coupled protons can be predicted using Pascal’s triangle. For example, a proton split by two magnetically equivalent neighbours will be a triplet with peak intensities of 1:2:1. The frequency difference between the lines of the multiplet is the coupling constant, J , reported in Hz, and is invariant with changes in the strength of the magnetic field. The greater accessibility to higher NMR field strengths has enabled the interpretation of many proton spectra as first-order. In symmetrical spin systems, these simple rules do not apply and a more rigorous analysis is needed.

The Pople spin notation system is generally utilized to indicate the degree of difference among nuclei. Thus, in a two spin system, AX indicates a molecule with two

Figure 3 Chemical shift spectra of 4-androsten-3,17-dione obtained from (a) the reflected J spectrum; (b) the purged J spectrum (the additional response near $\delta 1.7$ is from the residual water signal); and (c) the z -filtered J spectrum. The conventional ^1H spectrum is shown in (d). Reprinted with permission from Simova S, Sengstschmid H, and Freeman R (1997) Proton chemical-shift spectra. *Journal of Magnetic Resonance* 124: 104–121.

nuclei where the chemical shift difference is much larger than the coupling between them (weakly coupled system, first-order analysis possible), whereas AB indicates a molecule containing two strongly coupled nuclei with similar chemical shifts. An A₂BB' notation indicates a set of two equivalent nuclei (A) interacting with two nuclei (B, B') that are chemically, but not magnetically, equivalent.

For proton NMR, the most diagnostic couplings are 2-bond (²J, geminal), 3-bond (³J, vicinal), and 4-bond (⁴J, W-type) couplings. Geminal couplings can be quite large, but may not be evident due to the symmetry associated with the carbon and protons in question. As mentioned above, the lack of appearance of geminal coupling is due to the identical chemical shifts of the protons involved. Vicinal 3-bond proton–proton couplings tend to be the most useful when determining stereochemistry, although coupling beyond three bonds can be important in systems with ring strain (small rings, bridged systems) or bond delocalization, as in aromatic and allylic systems.

For simple organic molecules, pattern recognition of multiplets can simplify structure determination. For example, the presence of an upfield triplet due to three protons and a more downfield quartet due to two protons with the same coupling constant is most probably due to an ethyl group (X–CH₂CH₃). Therefore, it is useful to look for common patterns. Many preliminary assignments can be made in a standard 1D ¹H spectrum due to the reciprocity of coupling constants ($J_{AB} = J_{BA}$). With more complex patterns due to coupling to several magnetically non-equivalent protons, interpretation can be done via first-order analysis only if no two of the spins within an interacting multispin system have $\Delta\delta/J \leq 6$. Multiplets, such as doublet of doublets (dd), doublet of triplets (dt), triplet of doublets (td), doublet of quartets (dq), doublet of doublets of doublets (ddd), etc., can usually be analysed by first-order techniques, especially if the spectrum was run at a fairly high magnetic field. A very useful and practical guide to first-order multiplet analysis that utilizes either a systematic analysis of line spacings or inverted splitting trees to determine the couplings is listed in Further Reading.

Measurement of coupling constants can usually be done directly from the 1D spectrum with well-resolved multiplets, or aided by simple 1D homonuclear decoupling experiments where irradiation of one of the *weakly* coupled nuclei (i.e. nuclei with very different chemical shifts) simplifies a multiplet by eliminating that spin–spin interaction. Several two dimensional techniques also help to determine the coupling network, and determine and assign coupling constants. A 2D COSY (correlated spectroscopy) spectrum is a homonuclear experiment, and provides a map of the proton–proton *J*-coupling network in the molecule. The spectrum contains a set of auto-correlated peaks along the diagonal

($\omega_1 = \omega_2$), which is the original spectrum. For those spins that exchange magnetization due to *J* coupling, $\omega_2 \neq \omega_1$ and off-diagonal peaks appear. The diagonal peaks that correspond to *J*-coupled spins are connected by symmetrical pairs of off-diagonal peaks. In general, strongly coupled protons are handled better in a COSY experiment than with conventional 1D homonuclear decoupling. However, in molecules that have overlapping resonances, it can be difficult to accurately assign the cross peaks. Computer programs have been developed to provide automated processing and assignment of the data (see Further Reading). Further simplification of the spectrum can be attained by utilizing a DQF-COSY (double quantum filtered COSY) experiment, where singlets are essentially eliminated from the spectrum. Coupling constants can be attained from a COSY spectrum, but it is not a trivial process. The *J* values measured from a COSY spectrum also tend to be slightly larger than the actual *J* value.

The two-dimensional experiment, homonuclear *J*-resolved spectroscopy, is utilized to accurately measure the scalar coupling constants. This method can readily resolve overlapping signals, as well as strongly coupled systems. From the contour plot of the spectrum, multiplets are resolved along the *y*-axis (Hz), and the coupling constants are read directly along this axis. Projection of the multiplet onto the *x*-axis (δ -axis) provides a single resonance line for each distinct spin system without the effects of coupling (i.e. is proton-decoupled), and accurate values of δ (ppm) can be attained.

Stereochemical Assignments

Accurate stereochemical assignments are generally only possible in rigid or ring systems where free rotation about carbon–carbon bonds is hindered or not possible. As mentioned above, vicinal, three-bond couplings (³J) can be quite diagnostic of the stereochemical relationship between the coupling protons. The Karplus equation (eqn [1]) can predict the vicinal coupling constant ³J_{H–C–C–H} with reasonable accuracy if the H–C–C–H dihedral angle is known. Thus, dihedral angles near 0° or 180° have the largest coupling constants, while a dihedral angle of 90° has a coupling constant near 0 Hz.

$$\begin{aligned} {}^3J &= A \cos^2 \phi + C \quad (\phi = 0-90^\circ) \\ {}^3J &= A' \cos^2 \phi + C' \quad (\phi = 90-180^\circ) \end{aligned} \quad [1]$$

Use of this relationship in alkenes and ring (or bridged) systems works very well to predict stereochemistry. For alkenes, *trans* coupling is in the range of 12–18 Hz, and *cis* coupling is 6–12 Hz. See the texts listed in Further Reading for tables listing coupling constants in various alkenyl systems. *Trans*, diaxial protons on a six-membered carbocyclic ring have a dihedral angle

of $\sim 180^\circ$ and a J value of 6–14 Hz (typically 8–10 Hz), whereas protons oriented axial–equatorial or equatorial–equatorial with dihedral angles near 60° have coupling constants of 0–5 Hz (typically 2–3 Hz). In five-membered rings, vicinal *trans* and *cis* coupling constants may be similar in magnitude due to the reduced conformational flexibility of the ring relative to six-membered rings. Five-membered rings will adopt a twist conformation to relieve eclipsing interactions. For example, in the oxazo-

Figure 4 Oxazolidinones exhibiting coupling constants of $^3J_{4-5 \text{ cis}} = 7.2 \text{ Hz}$ and $^3J_{4-5 \text{ trans}} = 5.9 \text{ Hz}$.

lidinones in **Figure 4**, it was found that $^3J_{4-5 \text{ cis}} = 7.2 \text{ Hz}$, and $^3J_{4-5 \text{ trans}} = 5.9 \text{ Hz}$.

Where no coupling is possible because of a quaternary centre or if the coupling constants fall on the borderline between two possible orientations nuclear Overhauser effect (NOE) measurements may need to be taken in order to definitively establish the relative stereochemistry. The use of pulsed field gradients (PFGs) in the acquisition of NOE enhancement spectra now allows one to avoid the need to compute difference NOE spectra, as was done in the past. With NOE difference spectra, it was hard to avoid subtraction artifacts, and thus difficult to obtain accurate NOE values, especially small ($<1\%$) enhancements. Utilizing PFGs, the only resonances now seen in the spectrum are those from spins which are cross-relaxing with the irradiated spin.

The stereochemical assignments for the oxazolidinones in **Figure 4** were confirmed by the NOE enhancements of 13% between H4 and H5 in the *cis* isomer, and only 2% between H4 and H5 in the *trans* isomer. There was also an NOE enhancement of 5% between the CH_2 α to the phosphonate and H5 in the *trans* isomer. In the examples shown in **Figure 5**, the

Figure 5 NOE enhancements of two diastereomeric cyclic carbonates to confirm relative stereochemistries.

vicinal coupling constants were all small (0–3 Hz), thus indicating that all the methine protons were in axial–equatorial or equatorial–equatorial relationships. The NOE measurements indicated in **Figure 5** enabled final assignments of the relative stereochemistries.

^{13}C NMR

Information regarding the number and types of carbons in an organic compound can be provided by carbon NMR spectroscopy. Since the chemical shift range is greater for carbon than for proton, a greater dispersion of signals is seen. Different functional groups that contain at least one carbon, such as ketone, ester and amide carbonyls, alkenes, alkanes, alkynes, nitriles, imines, etc., can generally be readily distinguished by ^{13}C NMR spectroscopy. The chemical shifts of aromatic and alkene carbons, however, are in the same chemical shift range, and at times cannot be differentiated. This is in contrast to aromatic and alkene protons which exhibit different chemical shift ranges.

In general, the factors that affect the chemical shifts of carbons are the same as for protons (i.e. electron density around the nucleus in question, and anisotropy effects). Carbon chemical shifts can be readily calculated from tables of shift effects found in many texts. However, unlike protons attached to sp^2 carbons, sp^3 carbons attached to sp^2 carbons exhibit only a small shift difference. There are also few good substituent parameters available for calculating the chemical shifts of alkene carbons bearing polar groups, unlike the calculation of ^1H NMR chemical shifts near polar groups. However, in systems where resonance is present, some predictions can be made of relative shift differences in the carbons (see **Figure 1**).

Carbon–proton connectivities can be determined using several methods. The number of protons directly attached to the carbon in question will split the carbon resonance according to the $2nI + 1$ rule seen in proton NMR. There tends to be, however, much overlap of the

multiplets in fully proton-coupled carbon spectra, sometimes such that it is very difficult to distinguish between the various multiplets. Routine carbon spectra are therefore measured fully proton decoupled for simplicity. Information regarding the exact number of protons attached to the carbons can be acquired from APT, DEPT or INEPT experiments. In APT spectra, the carbons bearing an odd number of protons (CH , CH_3) can be distinguished from carbons with no or two attached protons (quaternary C , CH_2). DEPT and INEPT experiments can distinguish between all four types of carbons (primary, secondary, tertiary and quaternary). Heteronuclear 2D J -resolved spectroscopy can also be used to obtain the multiplicities of the carbons, as well as $^1J_{\text{C-H}}$.

A complete mapping of the protons to the carbons they are attached to is possible via a HETCOR (heteronuclear chemical shift correlation) experiment. This method correlates the peaks of the proton spectrum of a compound with the peaks of its carbon spectrum. A contour plot of the spectrum has a cross peak at the intersection of the vertical line drawn from a carbon resonance (plotted along the x -axis) with the horizontal line drawn from a proton peak (plotted along the y -axis). However, this method is relatively insensitive as it suffers from the low natural abundance of ^{13}C atoms in the molecule. Utilization of the inverse detection method, HMQC (heteronuclear correlation through multiple quantum coherence), can alleviate this problem as ^{13}C responses are observed in the ^1H spectrum. Normally, ^1H – ^{13}C coupling information is included in the ^1H dimension, although proton decoupling from carbon is possible. Quaternary carbons, however, will not be present in a HMQC spectrum. A method to aid in assignments of quaternary carbons, as well as carbon and proton connectivities, is the HMBC (heteronuclear multiple bond correlation) experiment. In these spectra, cross peaks are observed connecting the ^{13}C signals to ^1H signals two or more bonds away.

The INADEQUATE experiment is designed to map out the entire carbon skeleton of a molecule by providing

Figure 9 COSY spectrum of compound [6].

carbon–carbon connectivities, and offers great possibilities for organic structure determination. However, it suffers severely from the low natural abundance of covalently bound ^{13}C – ^{13}C pairs. Several groups have offered modifications of the pulse sequence to try to overcome this limitation. It remains to be seen, however, if these new programmes will produce the higher sensitivities needed for this experiment to become a routine analytical procedure.

Even without the newer modifications to the pulse sequence, the INADEQUATE experiment can be an invaluable method for structure determination in some cases, as illustrated in the example in **Figure 6**. The rearrangement of the cage hydrocarbon diazonium ion [1] in the presence of water could lead to three possible alcohol products [2], [3] and [4]. Only two alcohol products were obtained from this reaction in isolated yields of 38% and 7%. The structures of these two products could only be determined by the 2D INADEQUATE experiment due to the hydrocarbon nature of their structures, and therefore, the lack of any distinguishing details in the proton spectra. Each compound also had the same number of methylene, methine and quaternary carbons, thus precluding the utilization of structure determination by simple 1D ^{13}C spectroscopy.

The INADEQUATE and APT spectra for the major product are shown in **Figure 7**. In an INADEQUATE spectrum, the pairs of adjacent carbons, and hence the

connectivity, can be mapped out similarly to a COSY spectrum. The major difference here is that the original spectrum is not on the diagonal in an INADEQUATE spectrum (as in a COSY spectrum), but is in the x -axis direction (= normal ^{13}C frequencies) along the line $\nu_1 = 0$ (residual single quantum signals). The y -axis is the frequency ν_1 , the double quantum frequency that is the sum of the frequencies of the two coupled nuclei referenced to a transmitter frequency at zero. The peaks arising from two coupled nuclei (here adjacent carbons) with shifts ν_a and ν_b have coordinates of $((\nu_a + \nu_b), X)$, where X is the frequency of the carbon in a single quantum coherence spectrum (1D spectrum). At the double quantum frequency (ν_1) for each pair of adjacent carbons, doublets will occur at the coordinates of $((\nu_a + \nu_b), \nu_a)$ and $((\nu_a + \nu_b), \nu_b)$. Thus, the midpoint between each pair of signals lies on a line with slope of 2, and helps to distinguish the real peaks from artifacts. The (C7–C1) – (C1–C7), (C14–C8) – (C8–C14) and (C3–C5) – (C5–C3) peak pairs are illustrated on the spectrum (B) in **Figure 7**.

In the example illustrated in **Figure 6**, it may be noted that compound [3] would require the grouping $-\text{CH}_2\text{CH}_2-$ to be present, which is not seen in the INADEQUATE spectrum. For the major compound to be structure [4], the connectivity of carbon 1 would have to be to carbon 7 and the quaternary carbon, q. The connectivity found for carbon 1 was to carbon 7 and the methine carbon 12. Therefore, only structure [2] fully

NA = not available; ND = no NOE detected.

supports all the spectral data for the major isolated product from this rearrangement.

Putting It All Together

The following is an outline of the basic procedure that a practising organic chemist follows when deducing the structure of an organic compound via NMR spectroscopy. First, standard 1D ^1H and ^{13}C spectra are

acquired and analysed. If needed, a 'chemical shift spectrum' can provide a straightforward assignment of the δ value of all the resonances, including overlapping multiplets. Proton spin-spin couplings and near neighbours are either determined directly from the 1D ^1H spectrum, or assisted by homonuclear decoupling experiments. If these experiments are not conclusive due to overlapping resonances, changing the solvent or utilization of a shift reagent can on occasion resolve the overlapping multiplets. A map of the J -coupling network in

Figure 10 (a) ^{13}C spectrum of compound [6] (see Figure 2) in $\text{CDCl}_3/\text{benzene-d}_6$; (b) HETCOR spectrum of compound [6].

the molecule is available through 2D COSY or TOCSY experiments. Programs to assist in assignment of the cross-peaks in complicated COSY or TOCSY spectra are now available. Utilization of the DQF-COSY experiment eliminates all the singlets from the spectrum. The homonuclear 2D J -resolved spectrum allows for the separation of overlapping resonances and, therefore, accurate measurement of the coupling constants and chemical shifts. A number of ^{13}C experiments, such as APT, DEPT, INEPT, INADEQUATE, and heteronuclear 2D J -resolved experiments, can be run to assist in determining proton-carbon attachment, carbon-carbon attachments for carbon skeleton determination, and values of $^1J_{\text{C-H}}$. A 2D HETCOR spectrum will confirm the proton-carbon connectivities. Various NOE experiments can assist in determining stereochemical information whereas coupling constants cannot.

The following is an example that illustrates how several of the experiments listed above, as well as molecular mechanics calculations, can be used to deduce the structure of the compound produced by a photochemical rearrangement. The photochemical irradiation of the bicyclic compound [5] was run under sensitized conditions (acetophenone). Two possible products, [6] and [7], are theoretically possible, and are shown in **Figure 8**. The 1,3-acyl shift product [7] normally arises from photolysis under non-sensitized conditions, but can be formed from certain compounds under sensitized photolysis conditions. The oxa-di-pi-methane rearrangement product [6] was the desired compound. From 1D ^1H and ^{13}C NMR spectra, the only product isolated from the photochemical rearrangement did not appear to contain an olefin, as would be seen in the α,β -unsaturated ester [7]. Thus, the rearrangement most likely went via the oxa-di-pi-methane rearrangement, and not by the 1,3-acyl shift mechanism.

Further proof that the structure of the photoproduct was indeed [6] is as follows. From the standard COSY spectrum (**Figure 9**), all the proton-proton coupling networks could be established. The proton responsible for the peak at $\delta 4.22$ (d, $J = 4.8$ Hz) was coupled only to a proton at $\delta 3.06$ (dd, $J = 6.5, 4.9$ Hz), which in turn was coupled to only one other proton at $\delta 2.25$. Of the protons H_a – H_f , only proton H_a was expected to be coupled to only one other proton, namely H_b . The chemical shift of $\delta 4.22$ was also reasonable for H_a . The multiplet at $\delta 3.06$ was therefore assigned to H_b , and was coupled to one other proton at $\delta 2.25$. This other proton could be either H_c or H_d .

In order to assist in the assignments, the tricyclic structure [6] was submitted to molecular mechanics calculations to estimate the dihedral angles between the protons, and thus approximate the coupling constants using eqn [1] (see **Table 1**). According to these calculations, H_b and H_c had a dihedral angle of $\sim 13^\circ$ and thus

an estimated coupling constant of 7.5 Hz, while H_b and H_d had a dihedral angle of $\sim 110^\circ$ and an estimated coupling constant of 1 Hz. The measured J value between signals at $\delta 3.06$ and $\delta 2.25$ was 6.5 Hz, closely matching the calculated coupling constant between H_b and H_c . Therefore, H_c was assigned to the signal at $\delta 2.25$. This multiplet (ddd) exhibited three coupling constants of 14.0, 7.0 and 6.9 Hz. The large coupling of 14 Hz would be consistent with geminal coupling to proton H_d . The calculations predicted that in addition to H_b , H_c would couple to H_e with a dihedral angle of 32° and an estimated coupling constant of 6 Hz. H_f was predicted to be nearly orthogonal to H_c , and thus have little or no coupling to H_c . From this data, H_d was assigned to the multiplet at $\delta 1.99$ and H_e to the multiplet at $\delta 3.32$. From the COSY spectrum, the multiplet at $\delta 1.99$ was further coupled to the multiplet at $\delta 2.79$, which was assigned to H_f . The multiplet (dd) at $\delta 2.79$ had two coupling constants of 12.3 and 6.2 Hz. The large coupling constant was geminal coupling with H_e . The other coupling constant was consistent with the calculation of the dihedral angle of 35° between H_f and H_d . The protons H_g and H_h were coupled only to each other, and the exo proton H_g was assigned as the downfield doublet of doublets at $\delta 3.65$.

The distances between the protons of the proposed structure were also calculated by molecular mechanics and are summarized in **Table 1**. The photoproduct was submitted to NOE experiments to verify the spatial relationships. The signals assigned to H_a , H_b and H_c yielded meaningful data, and the NOE results are shown in **Table 1**. Results of the NOE experiments are in agreement with the proposed structure, where H_a , H_b , H_c and H_e are shown to be in a *cis* relationship.

The ^{13}C and HETCOR spectra in **Figure 10a** and **Figure 10b**, respectively, further verified the proposed structure [6]. No carbon signals were detected in the

Table 2 HETCOR data for compound [6]

Carbon	^{13}C δ	Proton(s)	^1H δ
C-1	63.7	H_a	4.23
C-2	43.7	H_b	3.06
C-3	26.5	$\text{H}_{c,d}$	2.25, 1.99
C-4	64.3	$\text{H}_{e,f}$	3.32, 2.79
C-5	68.8	$\text{H}_{g,h}$	3.64, 2.84
C-6	53.1	H_i	3.75

alkene region of the spectrum, consistent with the lack of alkene protons. The only carbonyl peak detected was at $\delta 207.6$, consistent with the ketone in [6]. The HETCOR data is summarized in **Table 2**.

Introduction

The majority of biological processes depend directly on peptides and proteins. The sequence of most peptides and all proteins are encoded genetically and the polypeptides are post-translationally modified, processed and transported to their specific location in the cell. The wide range of possible chemical structures (owing to the combination of functional groups of their amino acid residues), especially in their three-dimensional dynamic conformation, allows peptides and proteins to play many different roles in biological processes, such as hormone/receptor interactions, cellular adhesion and cellular recognition, transport mechanisms between cell compartments or through membranes, and the processing of almost all chemical compounds, including peptides and proteins, to name only a few.

Although the conformation and dynamics of peptides and proteins are encoded in their sequence, they are not

yet reliably predictable based on it. The determination of the dynamic 3D structure therefore was, and still is, of utmost importance for the interpretation and artificial modulation of their functions.

The challenges posed by peptides and proteins have strongly stimulated the development of modern NMR spectroscopy. Most of the multidimensional NMR techniques now available were designed and applied initially to peptides and proteins.

We will discuss in this article first some general problems which arise in the NMR spectroscopy of peptides. Then, NMR techniques for signal assignment and extraction of conformational parameters will be described, followed by a short excursion into structure determination using NMR parameters. The final part will include the analysis of peptide dynamics based on NMR data.

General Problems with Peptides

Peptides are composed of a linear, branched or cyclic array of amino acid residues (**Figure 1**). The peptide chain is defined and numbered from the N to the C terminus. The α carbon atoms of the amino acids are linked by peptide bonds. The bonds to the α carbon atom are described by their bond angles ϕ (N–C $^\alpha$), ψ (C $^\alpha$ –CO) and χ_1 (C $^\alpha$ –C $^\beta$). The usually planar peptide bonds prefer the *trans*-configuration ($\omega = 180^\circ$) as shown in **Figure 1** for the Phe-Gly and Gly-Val bonds. Only in the case of Xaa-Pro pairs are *cis*- and *TRANS*- conformations of similar energy. In **Figure 1** the Val-Pro bond is in the *cis*-configuration. The barrier between *cis* and *trans* peptide bonds is between 16 and 20 kcal mol $^{-1}$ which leads to a slow exchange between the conformations on the NMR time-scale at room temperature. At higher temperature the exchange between the two states occurs at an increased rate, leading to a coalescence of the two signal sets in NMR spectra.

Rotations around ϕ , ψ and χ_1 are fast on the NMR time-scale. As a result it is not straightforward to distinguish between a single preferred conformation and a rapid equilibrium between several conformations (see below). Linear peptides, approximately up to dodecamers, are normally very flexible and do not exist in or prefer a single conformation, although

Figure 1 Schematic representation of the tetrapeptide sequence – FVGP – used to illustrate the nomenclature.

sometimes a slight preference for a distinct set of structures is observed. However, cyclization and/or sterically demanding substitution restrain the conformational space and often allow the identification of a preferred conformation.

The equilibrium between the different conformations of a peptide can be very sensitive to the environment. Hence, different conformations can be found in a single unit cell of a crystal, between different crystals, between crystal and solution as well as between ‘free’ and receptor bound peptides. ‘Free’ conformations are embedded in the solvent whose chemical and physical properties can induce drastic changes when different solvents are used. The evidence for such conformational changes often is indirect (solvent induced signal shifts), but a careful analysis of the whole 3D structure can also lead to the detection of such exchange processes (see e.g. antamanide). Direct observation of solvent-induced conformational shifts is possible in the case of the *cis/trans* isomerization of an alkylated peptide bond, since rotation around this bond is slow enough to be resolved on the NMR time-scale. For example, when cyclosporin A is dissolved in CDCl_3 , benzene or THF one strongly dominating conformation is observed that contains a $\text{NMeVal}^9\text{-NMeVal}^{10}$ *cis* amide bond. The corresponding conformation with the same amide in the *trans*-conformation is populated at less than 5%. In more polar solvents, such as CD_3CN and MeOH, a number of coexisting conformations are found, whereas a single but very different conformation is found when the peptide is bound to the receptor. However, in cases of peptides with unmodified CONH peptide bonds *cis*-conformations are only very rarely observed.

Generally, it is recommended that proof of conformational homogeneity, i.e. the dominance of a single or a few conformation(s) under given conditions, be

obtained before beginning a detailed NMR analysis. Criteria for preferred conformations are:

- Large chemical shift dispersion within the set of H^{N} and H^{α} signals.
- Large shift difference between diastereotopic protons such as H^{α} protons of Gly, or of H^{β} protons in the side-chains of Phe, Tyr, His, Trp, Ser, Cys and the two β methyl groups of Val, for example.
- Strong differences in $\text{H}^{\text{N}}\text{-H}^{\alpha}$ coupling constants of different residues and $\text{H}^{\alpha}\text{-H}^{\beta\text{proR}}/\text{H}^{\alpha}\text{-H}^{\beta\text{proS}}$ coupling constants in each side-chain.
- Pronounced differences in NOE intensities.
- Appearance of long-range NOEs between protons of non-neighbouring residues.

Only if these criteria are met is it worthwhile initiating a careful conformational analysis. In general, conformational restraints, such as cyclization, binding to a receptor or complexation with metal ions, are necessary to fulfil these conditions.

If the NMR data indicate a flexible structure, a structural discussion is not meaningful since the bioactive conformation of interest, i.e. the conformation of the peptide bound at the receptor, is selected out of a large ensemble of alternative conformations.

Assignment of Signals

A prerequisite for the extraction of conformational parameters is the assignment of each signal in the spectrum to a specific spin system, and the assignment of these spin systems to specific residues in the peptide chain. The pulse sequences discussed here are shown in **Figure 2**.

Figure 2 Pulse sequences used in this article. All experiments can be acquired in the phase-sensitive mode, using either TPPI or the States method. Sequences 12 and 13 are best displayed in the magnitude mode because of phase modulation owing to homonuclear couplings in F_2 . All inverse correlations, except for sequences 12 and 13, can be preceded by a BIRD (bilinear rotating decoupling) pulse sandwich to allow for a fast repetition rate of scans. For simplicity gradients are not given here in most cases.

Assignment of Spin Systems

The COSY (correlation spectroscopy) experiment yields information about connectivity between nuclei. COSY cross peaks can be expected for each resolved scalar coupling between nuclei that are connected by two or three bonds. An unambiguous identification of individual amino acid spin systems can be complicated by the overlap of signals in the vicinity of the diagonal of the spectrum, overlap of cross peaks for the long side-chains of Arg, Lys, Pro and Leu and the frequently insufficient signal intensities of resonances that are coupled to many neighbouring nuclei (e.g. H^{γ} of Leu couples to eight vicinal neighbours). A list of other pulse techniques used in structural studies of peptides is given in **Table 1**.

The TOCSY experiment is the most efficient way to obtain complete assignments of spin systems (**Figure 3**). TOCSY is sometimes called HOHAHA.

The duration of the mixing period determines the efficiency of transfer. If a sufficiently long mixing time is

chosen, correlations of the whole proton spin systems are found. TOCSY experiments with short mixing times reveal mainly correlations between directly coupled nuclei.

The spin systems of the naturally occurring amino acid residues can be divided into two groups. While the side-chains of Ala, Arg, Gln, Glu, Gly, Ile, Leu, Lys, Met, Thr and Val exhibit unique spin systems and therefore can be identified with relative ease, the residues in the second group, including Asn, Asp, Cys, His, Phe, Ser, Trp and Tyr, all have similar AMXY proton spin systems. Nevertheless, the aromatic residues of the second group can be unambiguously assigned using H^{β} -H (ring) NOE cross peaks, whereas the Ser-spin system can be easily distinguished from all other possible AMXY spin systems in COSY experiments because of its weak H^{β} - $H^{\beta'}$ coupling. Trp is easy to identify via a heteronuclear HMQC experiment owing to its characteristic downfield shift of the β carbon signal.

Table 1 Pulse techniques necessary for structural studies of peptides

<i>Technique</i>	<i>Purpose</i>
P.E.COSY	COSY with simplified multiplet structure. P.E.COSY allows for the accurate measurements of homonuclear coupling constants
TOCSY = HOHAHA	Assignment of spin systems. If a long mixing time is used, TOCSY gives total correlation between all nuclei in a spin system
z-filtered TOCSY	TOCSY sequence that leads to cross peaks with pure phases. z-filtered TOCSY needs long measurement times owing to the random variation of the z-filter in 6 to 12 steps between 110 μ s and 20 ms
NOESY	NOESY gives distance information about nuclei that are separated by less than 500 pm in space
ROESY	ROESY is ideally suited for the observation of nuclear Overhauser effects for medium-sized peptides at low field strengths
HMQC	HMQC correlates the shifts of protons with a directly bound heteronucleus. Very sensitive
HMQC-TOCSY	HMQC with subsequent TOCSY transfer to coupled protons
DEPT-HMQC	DEPT-edited HMQC, which allows for the distinction of CH, CH ₂ and CH ₃ groups. Exclusive selection of these multiplicities is possible with the related HDQC, HTQC and HQQC techniques
ω_1 -filtered TOCSY = HETLOC	Extraction of coupling constants to proton-bearing heteronuclei. Because magnetization is distributed among a large number of spins, this method is rather insensitive
HQQC	Assignment of methyl groups in crowded spectra, when folding is not feasible
HMBC	Assignment of carbons and protons and determination of long-range coupling constants
Selective HMBC	Useful variation of HMBC. For peptides, the selective pulse is usually applied to the carbonyl carbons

Heteronuclear spectroscopy also reduces problems with signal overlap because of the large chemical shift dispersion of ^{13}C nuclei. The most popular heteronuclear correlation experiments for this purpose are HMQC and HMQC-TOCSY experiments (e.g. **Figure 4**). The latter contains information similar to the homonuclear ^1H -TOCSY, but, as for all heteronuclear experiments, its sensitivity is lower owing to the lower gyromagnetic ratio and low natural abundance of the ^{13}C nucleus.

HMQC sequences can be combined with DEPT editing, allowing for the editing of multiplicities in heteronuclear correlations. The resulting experiments, such as HDQC (heteronuclear double quantum correlation), HTQC (heteronuclear triple quantum correlation) and HQQC (heteronuclear quadruple quantum correlation), make it possible to exclusively excite CH, CH₂ or CH₃ groups. This results in a simplified assignment procedure.

An alternative way of overcoming problems with overlapping resonances in crowded spectral regions is to apply band-selective excitations. Band-selective pulses can be used to selectively excite a desired spectral region in one or more dimensions. The reduction of spectral width in one or more dimensions improves the digital resolution attainable in the chosen dimension, and thus helps to reduce ambiguities in the resonance assignment procedure. As a welcome side-effect it also shortens the measuring time of the experiment.

Resolution can further be improved substantially by semi-selective homonuclear decoupling during both the acquisition and the evolution dimensions. This can be achieved in the acquisition dimension by use of homonuclear shaped pulse decoupling in combination with the time-shared decoupling mode during data acquisition and in the evolution dimension by application of a semi-selective refocusing pulse together with a non-selective refocusing pulse in the centre of the evolution period.

An example of an experiment implementing these techniques is the BASHD- (band selective homonuclear decoupled) TOCSY experiment. Band selection in the evolution dimension is achieved by the excitation sculpting method. The key element of this method is a double pulse field gradient spin echo (DPFGSE) that leads to pure phase spectra with flat baselines. This cluster of pulses rephases only the selected magnetization affected by the 180° pulses and avoids any evolution of the J -coupling during this period. The combination of selective pulses and pulse field gradients to select the desired coherence pathway results in pure phase spectra largely devoid of artefacts. This principle can also be extended to any existing homonuclear and heteronuclear selective NMR experiment, as demonstrated by semi-selective 2D TOCSY, ROESY, HSQC and HSQC-TOCSY experiments.

Figure 3 (a) 500 MHz TOCSY spectrum of 20-mmol-L⁻¹ *cyclo*(-Tic-Pro-Phe-Gly-Pro-Pro-Thr-Leu-) in DMSO at 300 K with TPPI applied in the F_1 dimension. Mixing time was 80 ms. A number of relayed connectivities can be observed. This spectrum is typical for small cyclic peptides. Linear peptides of this size would exhibit much less chemical shift dispersion of H^N and H^Z protons. The indicated part of the spectrum is expanded in (b) which is the fingerprint region (F_2 : amide protons, F_1 : aliphatic protons); coupled nuclei are connected by dashed lines and assigned to the respective residues. (c) Sequence of *cyclo*(-Tic-Pro-Phe-Gly-Pro-Pro-Thr-Leu-). Tetrahydroisochinolin (Tic) is an unnatural proline like amino acid which lacks the amide proton.

Sequential Assignment

Sequential assignment of residues in a peptide chain requires correlation across the peptide bond that separates the proton spin systems of adjacent residues. This sequential information can be provided by dipolar couplings using NOESY or ROESY experiments, or by hetero-nuclear scalar couplings using HMBC experiments.

When only homonuclear proton experiments can be used (e.g. for reasons of sensitivity), NOESY or ROESY experiments are necessarily the method of choice. Short-range NOE signals, such as those observed between amide and aliphatic protons, are usually also observed for sequentially adjacent residues. Among these the

$H_i^N-H_{i+1}^N$ and $H_i^Z-H_{i+1}^N$ connectivities are especially important for establishment of the sequence (see **Figure 5**). In practice, however, ambiguities can be encountered in the sequential assignment step owing to overlap of cross peaks, particularly if the peptide contains multiple residues of one type, or if long-range NOE signals are also found in the H^Z-H^N region of the NOESY or ROESY spectrum, as in the case of folded peptides and small proteins. Sequential assignment of these molecules therefore can be ambiguous and requires a tedious and time-consuming analysis of the NOESY or ROESY spectra. In those cases, a significantly increased resolution in the H^Z-H^N region of the ROESY spectrum can be

Figure 4 500 MHz HMQC-TOCSY spectrum of *cyclo* (-Tic-Pro-Phe-Gly-Pro-Pro-Thr-Leu-) in DMSO at 300 K. Mixing time was 80 ms. In addition to the directly bound protons the entire spin system can be observed. Coupled nuclei are connected by dashed lines and assigned to their respective residues.

Figure 5 Part of the 500 MHz ROESY spectrum of *cyclo* (-Tic-Pro-Phe-Gly-Pro-Pro-Thr-Leu-) in DMSO at 300 K. Correlations between the amide protons and H^α protons of one residue and the H^α protons of the preceding residue are essential for the sequential assignment. Cross peaks between neighbouring amide protons are an important source of sequential information. Cross peaks not assigned belong to aromatic protons.

achieved with a BASHD-ROESY pulse sequence, incorporating band selection and homonuclear decoupling in the H^α region of the spectra. Band selection in the evolution dimension is performed with the DPGFSE technique as described above.

This NOE-based approach requires previous knowledge of the peptide sequence. The known sequential position of a residue with a unique or characteristic spin system can be used as a first 'anchor point', from which sequencing in both directions can be carried out. In cases where the sequence is unknown, a different strategy must be used. In this case, each spin system must be assigned individually to its type of amino acid *before* a sequential assignment can be achieved. Obviously this approach is restricted to relatively small molecules (up to 30 residues).

It is also possible to determine the sequence of a peptide using scalar coupling to the carbonyl carbon. This is best done with standard or selective HMBC experiments, where only carbonyl carbons are excited and indirectly detected during t_1 . The sequential assignment is then unambiguous and does not require any knowledge about the conformation of the peptide (**Figure 6**). A clear distinction between the proof of the complete assignment and the conformational analysis is then possible. Such

Figure 6 Polypeptide segment with the possible interresidue connectivities between spin systems. (a) Sequential short distance NOEs for peptides. (b) Observable through-bond couplings, useful for the sequencing of peptides.

a sequential assignment might also be used as an independent proof of the existence of a specific peptide bond, as for example formed by cyclization.

A complete assignment also includes the stereospecific assignment of diastereotopic groups such as methylene protons or geminal methyl groups in Val or Leu. Such additional information can significantly increase the quality of a 3D structure, which is especially important in the case of small peptides, where typically only a small number of long-range NOEs is available for the conformational analysis. Diastereotopic assignment will be discussed in more depth below.

Extraction of Conformationally Relevant Parameters

NOE Effects

Nuclear cross relaxation in liquids is caused by mutual spin flips in pairs of dipolar-coupled spins, induced by motional processes. Cross-relaxation efficiency depends on the spatial distances between the relaxing nuclei and leads to a transfer of magnetization between the spins. It causes intensity changes known as nuclear Overhauser effects (NOE). NOEs, as well as ROEs, can only be observed between nuclei that are separated in space by less than 500 pm. The NOE can be rationalized as heat flow from a non-equilibrium state to another neighbouring spin. In the NOE (or ROE) experiment such deviation from the Boltzmann equilibrium of spin states is created via specific pulsing and the efficiency of the heat flow to neighbouring nuclei (NOE build-up) is measured via the induced intensity changes of their NMR signals. The efficiency of dipolar relaxation is a function of the field strength (represented by ω_0) and the motion (rate of relaxation referred to the external magnetic field) of the molecule, described by the molecular correlation time τ_c .

The intensity of a cross peak appearing in a NOESY spectrum contains information about the relative distances

between the two nuclei that contribute to the cross peak. It can be shown that the cross-relaxation rate σ that determines the NOE transfer is obtained from eqn [1].

$$\sigma = W_2 - W_0 = \frac{\gamma^4 b^2 \tau_c}{4\pi^2 10 r^6} \left(\frac{6}{1 + 4\omega^2 \tau_c^2} - 1 \right) \quad [1]$$

where r is the internuclear distance and W_2 and W_0 are the transition probabilities for the double-quantum and zero-quantum transition respectively. At a given ω the variables that determine the size of σ are the correlation time τ_c and the interproton distance r_{ij}^6 . It should be noted that for specific combinations of τ_c and ω the second term becomes zero or negative. The build-up of cross peak intensity in a multispin system is given by $A(\tau_m) = \exp \{-R\tau_m\}$:

$$A_{ij}(\tau_m) = \left\{ -R_{ij}\tau_m + \frac{1}{2} \sum R_{ik}R_{ij}\tau_m^2 + \dots \right\} A_{ii}(0) \quad [2]$$

where $A(\tau_m)$ is the cross peak intensity as a function of the mixing time τ_m , R the relaxation matrix and R_{ij} the relaxation rate between spins i and j . For sufficiently short mixing times the quadratic term and those of higher order in τ_m can be ignored. The cross peak intensity is then directly proportional to the cross-relaxation rate and thus to the inverse sixth power of the distance between the nuclei (when the molecule behaves as a rigid body, $\tau_c = \text{constant}$):

$$A_{\text{NOE}} \propto \sigma_{ij} \propto \frac{1}{r_{ij}^6} \quad [3]$$

The intensities of NOE effects depend on the size of W_2 and W_0 . As can be seen for eqn [1] the NOE vanishes when $W_2 = W_0$, which occurs approximately when the inverse correlation time τ_c^{-1} is of the order of the Larmor frequency ω_0 .

Similar relationships can be derived for ROESY. In this case, the cross peaks are generated by cross relaxation of transverse magnetization. In the rotating frame, σ is given by eqn [4]

$$\sigma = u_2 - u_0 = \frac{\gamma^4 b^2 \tau}{4\pi^2 10 r^6} \left(\frac{3}{1 + 4\omega^2 \tau^2} + 2 \right) \quad [4]$$

where u_2 and u_0 are the transition probabilities for the double-quantum and zero-quantum transitions in the rotating frame, respectively.

It is important to note that ROE effects, in contrast to NOE effects, are always positive and never vanish.

NOESY as well as ROESY experiments can both provide distance information. However, there are some important differences in their application and in the evaluation of the resulting spectra.

The usefulness of either of these techniques depends strongly on the time-scale of the motional processes that cause the cross relaxation. We have to distinguish three

Figure 7 Dependence of the maximum NOE and ROE cross peak intensities $I_{k,\max}$ (standardized on a diagonal signal I_0) on ω and τ_c for very short mixing times.

cases: (a) the fast-motion limit (extreme narrowing limit) with a short correlation time $\tau_c \ll \omega_0^{-1}$ (positive NOEs) (Figure 7). This applies for small molecules in non-viscous solutions. (b) The slow-motion limit (spin-diffusion limit) with a long correlation time $\tau_c \gg \omega_0^{-1}$ (negative NOEs) which applies to large macromolecules such as proteins at the maximum currently used magnetic field strengths. (c) For intermediate sized molecules only small, or even no NOE, effects at all are observed. This is the case for peptides with a relative molecular mass of 500 to 1000 Da at resonance frequencies ω_0 of 300 MHz. Differences of internal mobility, for example via the rotation of side-chains, can then lead to the appearance of both positive and negative NOEs in the same NOESY spectrum, making it impossible to evaluate molecular distances from these data. If only small NOE effects are observed, the ROESY techniques should be used.

Two problems have to be considered in the evaluation of ROESY spectra. First, the offset dependence of the spin-lock field introduces intensity variations into the spectrum. Peak intensities will have to be corrected to take this effect into account when distances are to be calculated. The cross peak intensity as a function of offset from the transmitter (when NOE effects are neglected) is given by eqn [5].

$$A(\gamma B_l) = A \sin^2 \theta_k \sin^2 \theta_l \quad [5]$$

where $\theta_{k,l} = \arctan(\gamma B_l / \Omega_{k,l})$ and $\Omega_{k,l}$ are the offsets of spins k and l from the transmitter. The use of the compensated ROESY sequence leads to a higher intensity for peaks at the edge of the spectrum compared with the standard ROESY. In this case the peak intensity is given by eqn [6].

$$A(\gamma B_l) = A \sin \theta_k \sin \theta_l \quad [6]$$

Second, undesired TOCSY peaks appear because some nuclei that are spin coupled experience similar fields during the application of the spin-lock and fulfil the Hartmann–Hahn condition. Since the TOCSY peaks are

phase shifted by 180° with respect to the ROESY peaks, they can easily be recognized. However, the superposition of contributions from direct and indirect transfer results in a decrease of cross peak intensity and therefore in distances which are too long. When only lower boundaries are used as restraints in MD calculations this would lead to lower restraints and a less well-defined structure but would not induce wrong results. In addition, different internal correlation times, such as the above-mentioned different flexibility of the molecule, have a smaller influence in ROESY than in NOESY spectra.

NOESY spectra are preferred in the slow-motion limit but never near the transition from positive to negative NOEs ($W_2 \approx W_0$, $\sigma \rightarrow 0$) because the different internal mobility induces larger errors in distances. In such cases, lowering the temperature (to slow down molecular rotation) is recommended.

Evaluation of NOESY and ROESY Spectra

Dipolar cross-relaxation rates, and thus distances, can be determined through NOESY or ROESY experiments using various approaches. The measurement of build-up rates involves the recording of several NOESY spectra with different mixing times. To ensure equal conditions, the measurements should be made in succession. The integrals of cross peaks are determined, and the volumes are plotted as a function of mixing time:

$$A(\tau_m) = 1 - \exp(-\sigma \tau_m) \quad [7]$$

The derivative of eqn [7] at an extrapolated mixing time of zero yields the rate of build-up of the cross peak. This initial build-up rate is directly proportional to the cross-relaxation rate.

$$dA \frac{(\tau_m = 0)}{d\tau_m} = \sigma \quad [8]$$

The simplest and most common approach is the measurement of a single NOESY or ROESY spectrum with a short mixing time. At short mixing times the NOE build-up is in the linear range. Under this condition, it can be assumed that only direct enhancements σ_{ij} contribute to the cross peak intensity $a_{ij}(\tau_m)$. The evaluation of a single NOESY spectrum can be done by either integration of the cross peaks or in a more qualitative manner by visual inspection of the spectrum. The second approach is often used in the case of NOESY spectra of proteins where an insufficient signal-to-noise ratio and extensive overlap prevent the accurate integration of cross peaks. In large molecules ‘spin diffusion’, i.e. a rapid flow of magnetization from one nucleus via another nucleus to a third one, is the most severe problem. Only very short mixing

times can be used and a complete treatment of the relaxation matrices is recommended. In the first approximation the NOEs are only used qualitatively in proteins: cross peaks are then classified according to several semi-quantitative categories – usually strong, medium, weak – which correspond to distance ranges. This approach is not recommended for peptides since the integration of cross peaks should lead to considerably more accurate distances and spin diffusion is not so efficient in peptides as it is in large molecules. The so-called ISPA (isolated spin pair approximation) is closer to reality for molecules which are close to the $\tau_c \approx \omega_0$ condition.

Owing to the fact that absolute values of correlation times are usually not available, interproton distances cannot be directly calculated. Distances are instead obtained by calibration of the cross peak intensities against an internal distance standard, usually the distance between diastereotopic geminal protons (178 pm) or aromatic protons of Tyr (242 pm). Assuming isotropic tumbling and rigid-body model for all parts of the molecule, eqn [9] is then used to calculate all interproton distances:

$$r_{ij} = r_{\text{ref}} \left(\frac{a_{\text{ref}}}{a_{ij}} \right)^{-6} \quad [9]$$

Usually, the NOE enhancements for the structural and conformational analysis of peptides are extracted from 2D NOESY spectra. The GOESY experiment, a 1D version of the NOESY experiment, uses selective excitation of separated signals and yields accurate measurements even for tiny enhancements. The DPFGE NOE technique (see above) achieves better sensitivity by not discarding one of the coherence transfer pathways (in contrast to the GOESY technique), while spectra have the same characteristics as GOESY spectra. Therefore, the DPFGE NOE technique is to be preferred.

Determination of Coupling Constants

Many J -coupling constants illustrate a clear dependency on dihedral angles and therefore are an important source of conformational information. This relationship is particularly distinct for 3J -couplings. The model for the relationship between bond angles and the coupling constant most often used is that proposed by Karplus (Figure 8).

$$^3J = A \cos^2 \theta + B \cos \theta + C \quad [10]$$

The equation holds for almost all coupling constants (Table 2). Only the coefficients A , B and C have to be adjusted, depending on the type of the two coupled nuclei and their environment. However, even if the coefficients have been determined, the multiple angles that fulfil eqn [10] (up to four values can be obtained) remain a problem.

Figure 8 The Karplus curve for four coupling constants about the ϕ dihedral angle of an L-amino acid. There are four possible dihedral angles for a given coupling constant. Utilizing a combination of all four coupling constants it is usually possible to narrow down the choice to a single angle. Reproduced with permission of Wiley-VCH from Eberstadt et al. (1995) *Angewandte Chemie, International Edition in English* 34: 1671–1695.

Table 2 Coupling constants used to determine ϕ , ψ and χ_1 angles in peptides

Angle	Coupling constant
ϕ	$^3J_{\text{HN},\text{H}^\alpha}$, $^3J_{\text{C}^\beta,\text{HN}}$, $^3J_{\text{H}^\alpha,\text{CO}(i-1)}$
ψ	$^3J_{\text{HN}(i-1),\text{H}^\alpha}$
ϕ and ψ	$^1J_{\text{C}^\alpha,\text{H}^\alpha}$
χ_1	$^3J_{\text{H}^\alpha,\text{H}^\beta}$, $J_{\text{CO},\text{H}^\beta}$, $J_{\text{N},\text{H}^\beta}$

Despite these problems, the application of coupling constants, in addition to proton–proton distances, in modern conformational analysis of peptides is indispensable. In principle, the coupling constants shown in Table 2 can be used to determine the ϕ , ψ and χ_1 angles.

For the determination of homonuclear or heteronuclear three-bond coupling constants, three fundamentally different approaches are used: (1) direct measurements of splittings caused by J -couplings, (2) the so-called E.COSY-signal patterns in which the splittings can be measured as shift differences of signals and (3) special experiments which lead to modulation of signal intensities via J (Table 3). A frequent requirement for the latter is a ^{15}N -enriched sample, e.g. for the J -modulated (^{15}N , ^1H)-COSY experiment or the HNHA experiment. Whereas labelled compounds are routinely used for proteins and nucleic acids they are expensive for peptides and therefore rarely used.

Determination of Coupling Constants from The Shape of The Signal

All these techniques have to correct or compensate for the partial overlap of multiplet lines by either using

additional parameters which depend on the shape of the signals or by fitting a model to the overlapped experimental signal. However, this procedure requires that the line width is still smaller than the coupling constant, and furthermore that the signals have a good signal-to-noise ratio.

The determination of coupling constants from an antiphase (e.g. COSY) cross peak yields values which are inherently too large owing to the reciprocal signal cancellation of the antiphase pattern. Kim and Prestegard have described an especially simple method for the determination of coupling constants for AX spectra. The splitting of the maxima in the absorptive and in the dispersive signal is measured and the J -coupling is calculated via an extensive cubic equation (Figure 9). Only two calculations are required for the COSY spectra in which the phase are 90° shifted. This procedure is especially useful for the determination of coupling constants that cannot easily be extracted from peaks in E.COSY spectra (see below), e.g. for H^N-H^α cross peaks. No additional spectrum has to be recorded.

Table 3 Experiments that are used for determining the most important coupling constants in peptides

Coupling	Technique
H^N-H^α	Direct reading or Kim–Prestegard method
$H^\alpha-H^\beta$	E.COSY techniques
Couplings within the proline pyrrolidine ring	E.COSY techniques
$^{13}CO-H^\beta$	HMBC (qualitative), Keeler method
H^N-C^β	HETLOC

Figure 9 Determination of the separation of the signal maxima of an antiphase doublet for the absorptive (v_a) and dispersive (v_d) component. Based on these two parameters the coupling constant J can be calculated. Reproduced with permission of Wiley-VCH from Eberstadt et al. (1995) *Angewandte Chemie, International Edition in English* 34: 1671–1695.

The simulation of the line shape using a linear combination of reference signals is based on the simulation of a complex nonresolved multiplet, starting out from a library of experimental multiplets. This technique has found widespread application in the determination of heteronuclear long-range coupling constants from HMBC cross peaks of peptide samples with ^{13}C in natural abundance. The major advantage is the relatively high sensitivity of the HMBC experiment because of inverse detection, as well as the fact that the identity of heteronuclear couplings directly ensues from the assignment of the 2D cross signals. In principle, long-range coupling constants can be determined directly from the cross peaks which represent the active coupling. However, since the long-range heteronuclear coupling constants are approximately of the same magnitude as $^2J_{H,H}$ and $^3J_{H,H}$ coupling constants (1–10 Hz), the rather small heteronuclear antiphase coupling constant $^nJ_{C,H}$ cannot be read directly because of overlapping and reciprocal cancellation of the numerous multiplet lines. Keeler et al. have developed an elegant procedure which allows the determination of the heteronuclear long-range coupling constant from the line shape even in such cases (Figure 10). The difference between a cross section in an HMBC spectrum and the corresponding, reconstructed proton multiplet (e.g. from a 1D spectrum) is the heteronuclear coupling constant of interest. In practice, the proton multiplet will show some overlap in the 1D

Figure 10 Schematic of the Titman–Keeler method for the evaluation of heteronuclear coupling constants from HMBC spectra. The synthetic spectrum is computed from the homonuclear reference spectrum and a chosen heteronuclear coupling constant J_{trial} . This spectrum is then compared with the actual HMBC spectrum and J_{trial} is iteratively varied until a good fit is obtained. Reproduced with permission of Wiley-VCH from Kessler H and Seip S (1994) In: Croasmun WR and Carlson RMK (eds.) *Two-Dimensional NMR Spectroscopy*, pp. 619–654.

spectrum, and therefore a TOCSY spectrum with a pure phase (e.g. with a z -filter) has to be recorded. The homonuclear reference multiplet now differs from the HMBC multiplet only by the absence of the heteronuclear antiphase coupling and the signal amplitude. This can be simulated by scaling of the reference signal in the time domain with the term $\sin(\pi J_{\text{trial}} t)$. The amplitude and J_{trial} can now be varied by a nonlinear optimization until the deviation between the two spectra reaches a minimum. At this point J_{trial} should be equal to the coupling constant of interest.

This method has the advantage that a large number of coupling constants can be determined from a single HMBC spectrum, which usually contains a large number of long-range correlations. However, the quality of the heteronuclear spectrum and especially the signal-to-noise ratio is of crucial importance for the convergence of the optimization. Therefore, the method is time consuming with respect to both recording of the spectra as well as their processing, but it yields accurate values for the coupling constants between heteronuclei.

Assuming that the staggered rotamers are predominantly populated (Figure 11), qualitative considerations together with accurately determined homonuclear coupling constants are often sufficient for the diastereotopic assignment of methylene protons. The χ_1 angle can be set to -60° if the two $^3J_{\text{H}^\alpha, \text{H}^\beta}$ and $^3J_{\text{H}^\alpha, \text{H}^{\beta'}}$ coupling constants are small (both ~ 3 Hz). If one strong

and one weak coupling are observed, χ_1 can be either 60° or 180° . To differentiate these two cases, stereospecific assignment of the H^β protons is required. This is possible with the aid of qualitative heteronuclear J -couplings (e.g. between ^{13}C and H^β or ^{15}N and H^β) and NOE or ROE cross peak intensities to the different H^β protons.

Determination of Coupling Constants by The E.COSY Principle

The E.COSY (exclusive correlation spectroscopy) principle yields a simplified cross peak multiplet, since only the 'connected transitions' are excited. This means that the signal intensity in an A, M cross peak from a three-spin system AMX can only be found in those parts of the multiplet pattern where the spin states of the third nucleus X have been conserved. To obtain such an E.COSY pattern, a mixing of spin states of the X nucleus (e.g. by the application of a non-sensitive 90° pulse) must be avoided. The coupling between M and X can then be extracted from the passive coupling of the A, M cross peak as the shift of two in-phase multiplets, which are separated in the indirect dimension and, therefore, have no interfering influence on each other. The only requirement is that the splitting in F_1 (the coupling between A and M) must be larger than the line width (Figure 12).

The E.COSY technique with the highest sensitivity is P.E.COSY (primitive E.COSY), where the retention of the spin states of the passive spin is achieved using a

Figure 11 The three staggered conformers about the χ_1 angle of residues with β -methylene protons (see text for details).

Figure 12 H^α, H^β region of the 500 MHz P.E.COSY spectrum of cyclo(-Tic-Pro-Phe-Gly-Pro-Pro-Thr-Leu-) in DMSO at 300 K. The enlarged view is of the Phe³ H^α, H^β cross peaks. The displacement of the multiplet patterns can be used to determine the passive couplings with high accuracy. H^β means the low field β proton and $H^{\beta h}$ the high field proton.

small flip angle of the mixing pulse and subtraction of the dispersive diagonal via a reference spectrum. The resulting cross peaks contain strong signal intensities for connected transitions but vanishing intensities for non-connected transitions.

In heteronuclear spectroscopy E.COSY patterns can be easily obtained if no 90° pulse is applied to the heteronucleus (i.e. the states α and β are not mixed). ω_1 -Hetero-filtered (HETLOC) experiments are the method of choice for the determination of long-range coupling constants between protons and ^{13}C or ^{15}N nuclei in natural abundance that carry a directly connected proton (**Figure 13**). For the determination of the χ_1 angle the coupling $^3J_{H^\beta}$ can be determined by using a heteronuclear ω_1 -half-filter (X-half-filter) at the beginning of a NOESY or TOCSY experiment (before the t_1 delay). Only protons which are directly coupled to the magnetically active heteronucleus (^{13}C or ^{15}N) are selected, while ^{12}CH or ^{14}NH protons are suppressed. Obviously, no heteronuclear decoupling can be performed during the acquisition. The delay Δ is adjusted according to the value of the heteronuclear coupling constant for the ω_1 -half-filter ($\Delta = \frac{1}{2}J_{H,X}$) resulting in in-phase magnetization at the end of the two delays. The subsequent TOCSY sequence affects only the ^{13}C -coupled protons and transfers the magnetization through the entire spin system. In ω_1 the signals are split by the large value of the $^1J_{X,H}$ coupling (e.g. $^1J_{N,H} = 90$ Hz) in ω_2 by the desired long-range heteronuclear coupling constant. However, by this method heteronuclear $^nJ_{H,X}$ couplings can only be determined for heteroatoms which bear a directly bound

Figure 13 Part of the 500 MHz HETLOC (ω_1 -filtered TOCSY) spectrum of cyclo(-Tic-Pro-Phe-Gly-Pro-Pro-Thr-Leu-) in DMSO at 300 K. The enlarged view is of the Thr⁷ H^α, H^β cross peak. The coupling constant is extracted from the separation of the cross peak components in the better resolved acquisition dimension (F^2).

proton. The latter causes the required large splitting in ω_1 via $^1J_{X,H}$. Fortunately, using the sensitivity of an inverse detection experiment many heteronuclear coupling constants can be determined from a single spectrum for molecules in natural isotopic abundances.

Structure Determination of Peptides

The utilization of NMR data for the determination of the three-dimensional structure of peptides involves the use of computer simulations. The methods can be broken down into two general categories: molecular mechanics/dynamics (MM or MD) and distance geometry (DG) calculations.

MM and MD use a force field to describe the molecule and estimate the potential energy of the given conformation. The standard force field contains a term for distortion of bond lengths, bond angles and dihedral angles plus non-bonded terms for Coulombic interactions and a Lennard-Jones description of the attraction/repulsion of atoms. The application of experimental restraints is achieved by simply introducing an additional term, a so-called penalty function. This penalty function serves to minimize the differences between the calculated values and experimental data.

The second general approach, DG calculations, utilizes a description of a molecule based solely on distances. Bond lengths, bond angles and torsion angles are converted into ranges of allowed distances according to the molecular constitution. Distances which satisfy these ranges are chosen randomly to create a distance matrix.

The diagonalization of this matrix then produces Cartesian coordinates. The experimental distances are compared with the distances generated from DG calculations based on the covalent structure; if the experimental distances are tighter, they replace those on the consideration of the covalent geometry.

The most important parameters for the determination of a three-dimensional structure are NOE-derived distances, bond angles derived from J -coupling constants and temperature dependences of H^N proton chemical shifts. Distances from NOESY or ROESY spectra are directly used as restraints for the calculations. Recently, coupling constants have also been used in computational structure refinement. The penalty function employed in this case is directly based on the Karplus equation. If more than one coupling for a single dihedral angle is available, the restraints from coupling constants are quite useful at the level of structure refinement. A limited number of experimental NOE values for peptides normally requires special care. In small peptides more or less all of the protons are on the surface, in contact with the solvent, and thus there are only distances to one side whereas in proteins there are many protons in the core region that are completely surrounded by other protons. Hence, for peptides it is indispensable to collect as much experimental data as possible. This means that accurate, quantitative NOE data as well as correct treatment of J -coupling constants are required.

The direct application of the temperature coefficients in structure refinement is problematic, since, while a temperature coefficient may indicate that an H^N proton is shielded from the solvent (for example by being involved in a hydrogen bond), it does not allow for identification of the acceptor of that hydrogen bond. Therefore, temperature coefficients, unfortunately, are frequently used only to confirm the final structure. The analysis of the radial distribution function (rdf) of the solvent around an amide proton shows, in our experience, distinct peaks when this proton is solvent exposed. The size and sharpness of these rdfs correlate directly with the size of the temperature gradient.

Conformational analysis of a peptide normally begins with the simple assumption of only a single dominating conformation using restrained MD under vacuum, beginning with various starting structures (to prevent structural bias, it is, however, recommended to begin with DG calculations to create the first crude starting structures for the MD). The resulting MD structure is further refined by recalculations of the molecule within an explicit solvent box. This can contain H_2O , DMSO, $CHCl_3$, CH_3OH or others, depending on the solvent used for the measurement. The best procedure uses a truncated octahedron to allow periodic boundary conditions for an almost spherical box but also cubic boxes may be used. The quality of the final structure is finally checked by

a long trajectory MD calculation (100 ps or more), without all experimental restraints but within the solvent. If all restraints are fulfilled (within about 10 pm), and the same result is always obtained regardless of the selected starting structure, it can be concluded that a 'single' satisfying conformation exists (a 'single conformation' may still include some flexibility, of the order of $\pm 20^\circ$ for torsions). There might be other conformations which also fulfil the experimental data, especially when the system is underdetermined owing to an insufficient number of constraints, but this should be apparent if different starting structures lead to different results.

If one part of the molecule turns out to be well defined while another part shows larger deviations from the experimental constraints, it can be assumed that the latter part is undergoing intramolecular motion that is fast on the chemical shift time-scale. Short distances r contribute most strongly to the observed NOE intensities (because of the r^{-6} dependence), and hence not all distance constraints derived from NOEs can be fulfilled at the same time if an equilibrium among several conformations exists. Given that there is a sufficient number of restraining parameters one can try to analyse this equilibrium by using time-dependent NOEs and/or time-dependent coupling constants, making the assumption that the constraints are not fulfilled at each simulation step, but rather only over a whole trajectory. This allows for analysis not only of the flexibility but also of the detailed nature of the molecular processes involved.

In addition, ensemble calculations may be used to analyse flexible structures. However, these calculations are time consuming, difficult to analyse and cannot directly include solvents. Hence, this procedure is only used in rare cases.

Side-chain mobility is analysed mainly by assuming a rapid equilibrium between three staggered conformations. The populations of the conformations can then be derived from the homonuclear and heteronuclear coupling constants using Pachler's equation. The observed coupling J_{obs} then results as the average over all three rotamers, J_i , weighted with their respective population P_i .

$$J_{obs} = \sum_i P_i J_i \quad (i = 1-3) \quad [11]$$

$$P_{[1]} = \frac{J(H^\alpha, H^{\beta_{proR}}) - J_{sc}}{J_{ap} - J_{sc}} \quad [12]$$

$$P_{[2]} = \frac{J(H^{\beta_{proR}}, CO) - J_{sc}}{J_{ap} - J_{sc}} \quad [13]$$

$$P_{[2]} = \frac{J(H^\alpha, H^{\beta_{proS}}) - J_{sc}}{J_{ap} - J_{sc}} \quad [14]$$

$$P_{[3]} = \frac{J(H^{\beta_{proS}}, CO) - J_{sc}}{J_{ap} - J_{sc}} \quad [15]$$

For homonuclear couplings, the antiperiplanar coupling J_{ap} is 13.6 Hz and the synclinal coupling J_{sc} is 2.6 Hz while for heteronuclear ^1H – ^{13}C couplings J_{ap} is 8.5 Hz and J_{sc} is 1.4 Hz. It should be noted that homonuclear coupling constants and NOE effects alone do not always yield an unambiguous diastereotopic assignment of the β -methylene protons. This means that incorrect values for the dominant bond angle (χ_1) may be obtained. This is especially the case if MD calculations are performed only under vacuum. In such cases, a globular structure is often predicted for the molecule, which only opens into a realistic conformation when the solvent is explicitly included in the calculations. Especially as peptides have a large surface which can interact with the solvent, it is essential to perform MD calculations in explicit solvents.

Relaxation Parameters and Molecular Dynamics

NMR spectroscopy is uniquely capable of comprehensively characterizing the internal motions of peptides in solution at the atomic level over time-scales ranging from picoseconds to hours. NMR techniques used for the study of dynamics include relaxation rate measurements, dynamic NMR and line shape analysis, magnetization transfer experiments, NOESY and ROSEY and amide proton exchange measurements.

For diamagnetic peptides in isotropic solvents, the primary mechanism of nuclear magnetic relaxation of protonated ^{13}C nuclei and of ^{15}N nuclei at natural abundance is the dipolar interaction with the directly bound protons. At high magnetic fields, chemical shift anisotropy (CSA) also contributes to the relaxation of the heteronuclei. The rates of these relaxation processes are governed by both the internal motions and the overall rotational motion of the molecule. Consequently, characterization of ^{13}C and ^{15}N heteronuclear relaxation can provide information about internal dynamics of peptides on time-scales faster than the rotational correlation time.

The $T_{1\rho}$ times of protons have been measured to study conformational exchange on the microsecond to millisecond time-scale. However, the complex interaction with surrounding protons, which is strongly dependent on the molecular geometry, may lead to artefacts in the interpretation of the data.

The overall tumbling rate, an important parameter for NMR spectroscopy, can best be determined by measuring T_1 relaxation times. To determine the overall correlation time τ_c at least two different field strengths are required. In most cases, the function (T_1 versus τ_c) allows for two possible values of τ_c . Usually the true τ_c can be selected based either on reasonable estimates as a function of relative molecular masses or after consideration of

Figure 14 Dependence of T_1 on τ_c at two different field strengths. The different T_1 times [$T_1(1)$ and $T_1(2)$] clearly correspond to $\tau_c(1)$; the alternative values for τ_c can be ruled out.

additional relaxation rates such as T_2 relaxation times or heteronuclear NOEs (**Figure 14**).

Specific models for internal motions can be used to interpret heteronuclear relaxation, such as restricted diffusion and site-jump models. However, model-free formal methods are preferable, at least for the initial analysis, since available experimental data generally are insufficient to completely characterize complex internal motions or to uniquely determine a specific motional model. The model-free approach of Lipari and Szabo for the analysis of relaxation data has been used for proteins and even for peptides. It attempts to reproduce relaxation rates by a weighted product of spectral density functions with different correlation times τ_i . The weighting factors are identified as order parameters S_i^2 for the molecular rotational correlation time τ_c and optional further local correlation times τ_i . The term $(1 - S_i^2)$ would then be proportional to the amplitude of the corresponding internal motion. However, the Lipari–Szabo approach is based on the assumption that molecular and local correlation times are not coupled, i.e. they should be distinct enough (e.g. differing by at least a factor of 10 in time) to allow for this separation. However, in small molecules the rates of these different processes are of the same order of magnitude, and the requirements of the Lipari–Szabo approach may not be fulfilled. Molecular dynamics simulation provides a complementary approach for the interpretation of relaxation measurements.

Scope and Applications

Information on the structure of drug molecules and their interactions with their therapeutic sites of action is of critical importance in the design and development of new drugs. Of all the analytical methods, nuclear magnetic resonance spectroscopy (NMR) is the most exquisitely suited to provide such experimental results. The field of NMR is advancing continuously to include new pulse sequences and methods as well as progressively larger field instruments and improved probes. This fast progress in NMR methods and technologies has served to expand dramatically its applications in drug research. Indeed NMR, used jointly with X-ray crystallography and computational/graphical approaches, has revolutionized structure-based drug design.

Currently the availability of a plethora of multi-dimensional/multinuclear NMR methods allows us to extract information on the structures and dynamic behaviours of a wide range of drug molecules of up to 30 kDa in size. These include the small and medium-sized traditionally used therapeutic drugs, to higher molecular weight peptides, proteins, nucleotides, nucleic acids and polysaccharide biotechnology products.

Progressively, more detailed structural and dynamic information has become available because of our increased ability to measure more effectively the basic NMR parameters used in structural analysis, namely, proton and carbon chemical shifts, coupling constants, relaxation parameters (T_1 , T_2) and the exceedingly valuable nuclear Overhauser effect. Such measurements are, in turn, used to obtain information on the three-dimensional structure of molecules as well as their conformational properties and dynamic behaviour. Additionally, the new solution NMR

methods allow researchers to study the interactions of a drug molecule with its site of action on the biopolymer (enzyme, receptor, nucleic acid, etc.). Such studies can lead to insights regarding the bioactive conformation of a flexible drug molecule, which constitutes invaluable information for drug design. Here we shall discuss the most commonly exploited experiments for extracting the individual NMR parameters mentioned above, and also how such parameters are utilized to obtain structural information.

Conformational Analysis of Small Molecules

Information on the structural properties of small drug molecules in solution can be obtained from a number of NMR parameters including ^1H and ^{13}C chemical shifts, ^1H – ^1H and ^1H – ^{13}C scalar coupling constants, ^1H nuclear Overhauser effects (NOEs), as well as relaxation measurements. Here, the conformational analysis of CP55,940 (Figure 1) is used to illustrate the most common experiments encountered in studying small molecules (<1000 Da) in solution. This synthetic compound is structurally related to Δ^9 -tetrahydrocannabinol (Δ^9 -THC), a psychoactive component of marijuana, and which has received much attention because it was used as the high affinity radioligand during the discovery and characterization of the G-protein coupled cannabinoid receptor (CB1). The elucidation of the conformational properties of this compound and its congeners provides information on the steric requirements for a productive interaction at the cannabinoid receptor active site.

Double Quantum Filtered Correlation (DQF-COSY) and Total Correlation (TOCSY) Spectroscopy

These experiments provide information on ^1H chemical shifts and ^1H – ^1H scalar coupling. Spectral assignments are made initially by an analysis based on integrated peak areas and chemical shifts in the one-dimensional spectrum. Subsequently, they are specifically assigned by analysis of scalar or spin–spin coupling connectivities observed by ^1H – ^1H double quantum filtered correlation spectroscopy (DQF-COSY). This is a two-dimensional experiment where the information is spread onto a plane

Figure 1 The one-dimensional ^1H spectrum of CP55,940 with an expanded scale of the aromatic region. The molecular numbering system for assigning the peaks is shown.

in which the diagonal is equivalent to the one-dimensional spectrum, and the scalar coupling is manifested as an off-diagonal crosspeak between the two resonances in question. Thus even though a resonance may not be visible in a one-dimensional spectrum due to overlap, its position may be identified from a crosspeak in a two-dimensional experiment. Protons that are part of a spin system often give rise to a pattern of diagonal peak–crosspeak connectivities that can be traced from a ‘starting point’ in the spin system to an ‘end point’. It is the presence of such connectivity patterns that makes this experiment such a powerful tool in assignment.

For example, the ^1H NMR spectrum of CP55,940 is shown in **Figure 1**. A logical starting point for assignment was the resonance at δ 3.74 that was assigned to H9a because the size of the peak as measured by integration was consistent with one proton and because this aliphatic resonance is expected to be deshielded. In the DQF-COSY spectrum (**Figure 2**) vicinal coupling to H10e, H8e, H10a and H8a is observed. Assignment of H10e and H10a resonances was made with the support of the crosspeak connectivities of H9a with H10a, H10e, H8a and H8e. The DQF-COSY spectrum clearly shows three components (H10e, H8e and H11e) under the multiplet at δ 2.06, in which three related strong geminal 2J couplings, H10e/a ($F_1 = \delta$ 2.09, $F_2 = \delta$ 1.38), H8e/a ($F_1 = \delta$ 2.05, $F_2 = \delta$ 1.53) and H11e/a ($F_1 = \delta$ 1.98, $F_2 = \delta$ 1.13) can be

discerned. This is a prime example of the improvement in spectral resolution of two-dimensional experiments over one-dimensional experiments.

Complete assignment of a whole spin system may be limited because of severe spectral overlap. To overcome this, DQF-COSY data are often used in conjunction with total correlation spectroscopy (TOCSY). This experiment results in a transfer of magnetization across an entire spin system and consequently crosspeaks may be observed between each resonance of a spin system. Thus it is possible to determine whether a particular overlapped region of the spectrum contains all unidentified members of a chemical spin system.

^1H chemical shifts and scalar coupling constants can be measured directly from one-dimensional spectra if the peaks are well resolved, or, if spectra are too complex, they may be measured from DQF-COSY spectra crosspeaks. However, such measurements are often inaccurate and so are used as a basis of simulating the observed 1D spectrum to obtain more accurate values. The measurements are used as a starting point and are systematically altered until the simulated spectrum best matches the observed spectrum. ^1H – ^1H scalar coupling constants are especially useful in providing information on the dihedral angle within a HC–CH system and are thus one of the most important sources of conformational information.

Figure 2 Contour plots of expanded regions from the DQF-COSY spectrum of CP55,940. The lines highlight the connectivities between the H8, H9a, H10 and H11 resonances.

Nuclear Overhauser Effect Spectroscopy (NOESY)

The nuclear Overhauser effect (NOE) is another important NMR parameter used in conformational analysis because the magnitude of the NOE is inversely proportional to the sixth power of the interproton distance in space ($I_{\text{NOE}} \propto r^{-6}$). NOE spectroscopy (NOESY) is a two-dimensional experiment that may be run routinely in which the NOE is manifested as a crosspeak between two resonances indicating that the two protons are near in space.

For example, in the case of CP55,940, two NOE crosspeaks were assigned to the spatial coupling of H5 with H8a and H12a (Figure 3). Such crosspeaks are congruent with a conformation in which the planes of the two rings are almost perpendicular, with the Ph-OH oriented towards the α face of the cyclohexyl ring. An NOE crosspeak between the phenolic hydroxyl proton and the adjacent aromatic H2 indicates that these two protons are spatially near each other and thus coupled through a dipole-dipole interaction (Figure 3). Such a result indicates that in its preferred conformation, the Ph-OH proton points away from the cyclohexyl ring and towards the H2 proton.

The full analysis of NOESY and DQF-COSY spectra of other analogues, plus computational studies, further showed that this was typical for all congeners of CP55,940 and that the dimethylheptyl chain adopts one of four preferred conformations, in all of which the chain is almost perpendicular to the phenol ring. The most biologically active conformations were such that all hydroxyl groups were oriented towards one face of the cyclohexyl ring system (Figure 4), a feature that may be an important requirement for cannabimimetic activity.

Identification of Drug Metabolites

One major use of NMR spectroscopy in the pharmaceutical sector is as part of a concerted and integrated effort, together with mass spectrometry MS, to identify the metabolites of both candidate and marketed drugs. It is an important part of any drug development process to be able to understand the metabolism of a candidate drug in several animal species. All of the usual structural tools of NMR spectroscopy can be used, but often the very limited availability of material, usually isolated from urine, bile or faecal material, means that NMR spectroscopy is often

Figure 3 Contour plot of the 500 MHz CP55,940 NOESY spectrum in CDCl_3 . The NOE interactions for CP55,940 are indicated with arrows.

Figure 4 Representation of the active biological conformation of CP55,940. According to the current hypothesis, the ligand preferentially partitions in the membrane bilayer where it assumes an orientation and location allowing for a productive collision with the active site.

limited to one-dimensional ^1H spectra. If a drug molecule contains a fluorine or a trifluoromethyl substituent, both quite common, then ^{19}F NMR spectroscopy can be very useful.

Rather than extract the substance of interest from its biological matrix it is now also possible to conduct HPLC separations with on-line NMR detection. The most comprehensive approach is to also couple a mass spectrometer in parallel to the NMR instrument, splitting the chromatographic eluate 95:5 to the NMR and MS, respectively.

NMR spectroscopy can also be used to investigate certain drug metabolites that show chemical reactivity,

and hence might cause toxicity by interacting with proteins. NMR spectroscopy has been used extensively for this in the case of drug acyl glucuronide conjugates, where the initially formed 1- β -O-acyl glucuronide of a carboxylate containing drug can spontaneously react to form isomers in which the drug moiety has migrated around the glucuronic acid ring. These isomers have been postulated to react with proteins and cause immunological toxicity. Hence, the rate of reaction has been measured for a number of such real and model drugs, especially for non-steroidal anti-inflammatory drugs, in order to develop structure–reactivity relationships.

Structure of Drug Macromolecules

An increasing number of therapeutic drugs are composed of proteins or peptides and knowledge of their three-dimensional structures has helped in the design of structurally modified variants with improved biological activities and pharmacokinetic properties. Such a case is insulin, which was first extracted from pancreas tissue, used in a patient in 1922, and its structure first determined in 1972. It has a molecular weight of 5.8 kDa and consists of a 21 amino acid peptide (chain A) that is connected to a 30 amino acid peptide (chain B) by two disulfide bonds. A third intra-subunit disulfide bond exists in chain A.

Figure 5 The 500 MHz ^1H DQF-COSY spectrum of a shortened analogue of insulin, des-(B26–B30)-pentapeptide insulin in D_2O . The spectrum was recorded on a Bruker AM 500 spectrometer in a phase-sensitive mode. 2048 complex data points were acquired in the t_2 dimension, with a total of 512 free induction decays (FID) collected for transformation in the t_1 dimension. Each FID was acquired with a total of 128 scans.

The structure of insulin has been probed using X-ray crystallography, while NMR spectroscopy was used to determine its three-dimensional structure in solution. As with other similar-sized molecules, standard two-dimensional ^1H homonuclear experiments can adequately provide such structural information.

The use of two-dimensional experiments such as DQF-COSY, TOCSY and NOESY to assign and determine the three-dimensional conformation of peptides and proteins is well established. Briefly, the method used for the assignment of amino acid chains is not dissimilar from that of assigning small molecules. Each amino acid residue gives rise to a characteristic spin pattern that can be identified using the complementary DQF-COSY and TOCSY spectra, where connectivities between all protons within a spin system are observed in the TOCSY, and connectivities between neighbouring protons are observed in the DQF-COSY. An example of the DQF-COSY spectrum for the des-pentapeptide insulin monomer is shown in **Figure 5**. Of the 46 amino acids in the monomer, non-overlapped spin systems for four valine, two glycine, one threonine and one alanine residue were distinguished. The latter two were sequence specifically assigned as threonine-8 in the A chain and alanine-14 in the B chain as these were the only alanine and threonine residues in the sequence. In addition, a further nine AMX spin systems could be clearly distinguished that were subsequently assigned to amino acids with the aid of the TOCSY and NOESY spectra.

Figure 6 The fingerprint region of a 500 MHz ^1H NOESY spectrum which contains NOEs between NH and H_α resonances of des-(B26–B30)-pentapeptide insulin. The expected intra-residue and inter-residue NOEs that form the highlighted sequential pattern of B chain backbone NH and H_α resonances are represented as solid and dashed arrows, respectively.

A combination of DQF-COSY and TOCSY data were required in order to delineate the remaining overlapped amino acid spin systems.

Once the spin systems arising from individual amino acids have been identified, the correct sequence of amino acids is determined from NOE data, acquired using the NOESY experiment. For molecules that fall within a particular molecular weight range (1000–3000 Da), the magnitude of the NOE is small, and a modification that is referred to as rotating Overhauser enhancement spectroscopy (ROESY) must be employed. Typically, a series of NOESY (and/or ROESY) spectra are collected in different solvents such as D_2O , H_2O or DMSO, with mixing times ranging from 50 to 600 ms. Different mixing times are required to gain an estimate of the magnitude of the NOE and subsequently an estimate of the distance between the protons. Care must be taken at longer mixing times, as it is possible to observe an indirect magnetization transfer between protons that are further apart than 5 Å via a third proton that is appropriately positioned between them. To avoid this spin diffusion effect, it is preferable to acquire NOESY experiments with the shortest mixing times possible that will result in good quality spectra.

The determination of the amino acid sequence is based on the fact that NOEs will always be observed between particular protons from neighbouring residues regardless of the secondary structure of the protein. For example the proton attached to the α carbon (H_α) of an

amino acid will always be within approximately 4.5 Å of the proton attached to the nitrogen (NH) of the neighbouring amino acid that is attached to the carboxyl end. In the NOESY spectrum, the NH resonances tend to occur within a particular spectral region, as do the H α resonances. Thus, there is a particular region of cross-peaks between them in which a continuous connectivity pattern can be distinguished that begins with an NOE between the first and second residue and ends with an NOE between the terminal residue and the one preceding it (**Figure 6**). Such patterns reveal the sequence of amino acids in the protein. Similar patterns can also be distinguished between other groups of resonances (e.g. correlations between NH protons of neighbouring residues, H β protons and NH protons of neighbouring residues) that can be used to confirm the sequence or resolve ambiguities. Breaks in this continuous pattern do occur in cases where resonances overlap or in some instances due to the structure of the amino acid chain, for example when a proline is present. However, once various lengths of polypeptides have been identified it is usually possible to surmise the order in which the various lengths are connected. This is achieved by considering different possibilities until a process of elimination arrives at the arrangement that best fits the data.

Once the spectra have been assigned, data that contain structural information can be extracted. Nuclear Overhauser effects between non-neighbouring residues are the most revealing source of conformational information, and scalar coupling constants are important in providing information on torsion angles. All such conformational parameters are used as constraints in computational calculations that arrive at the three-dimensional conformation of the protein. For small molecules, such as the non-classical cannabinoids, it is possible to infer the conformation from NMR data without the aid of a computer, given that there are a relatively small number of NOEs generated and there are limited conformational possibilities from which to choose. However, for peptides, proteins and other macromolecules such as DNA, where a large number of measured NMR parameters must be taken into consideration, computational methods are an essential tool in the determination of the vast conformational possibilities. The computational techniques utilized seek to systematically adjust the position of all nuclei in the molecule, so that all distances and bond angles derived from NOE data and coupling constants are satisfied. At the same time, the structure must not exceed set physical limits for bond lengths, bond angles, torsion angles, van der Waals contacts and Coulombic interactions between atoms. The challenge in such methods is to ensure that all possible conformations are sampled while not allowing the molecule to exceed the set physical limits. Various algorithms and methods for calculation exist; however, the most

common are the distance geometry and/or restrained molecular dynamics methods.

Using this basic methodology, the three-dimensional conformation of insulin was determined, and a significant amount of structure–activity information was gained by the study of insulin analogues and insulins purified from different sources.

Structural Analysis of Drug-Binding Domains

Macromolecules such as proteins and nucleic acids form the sites at which drugs interact. Knowledge of three-dimensional conformations assists in the design of analogues that are more potent and have improved pharmacokinetic properties. Furthermore, the structural analyses of protein receptors and enzymes add to the knowledge of biological systems, and therefore assist in identifying novel types of therapeutic agents. Because of their large molecular weights, most macromolecular therapeutic targets cannot be studied using exclusively ^1H homonuclear methods.

The advent of three-dimensional and heteronuclear pulse techniques has greatly expanded the ability to study macromolecules of up to 30 kDa in size. Three-dimensional techniques are a natural progression of the two-dimensional experiments. The pulse sequence is altered so that a vertical domain is introduced and the information is spread into a third dimension, so that the spectrum now is projected into a cube instead of a plane. The diagonal of the cube is equivalent to the one-dimensional spectrum, and crosspeaks that may be overlapped in a two-dimensional spectrum can be resolved in the third dimension.

A case in point is the structure determination of the insulin receptor substrate-1 (IRS-1). Insulin binds to a membrane-bound receptor that is a ligand-activated protein tyrosine kinase. Upon insulin binding there is an autophosphorylation of several tyrosine residues on the cytosolic side of the receptor. This enhances the tyrosine kinase activity of the insulin receptor towards other substrates and is required for signal transduction. A cascade of events is initiated, the first of which is the phosphorylation of IRS-1. This occurs when IRS-1 binds to the insulin receptor via a specific domain of the protein that is termed the phosphotyrosine binding (PTB) domain.

The structure of this domain was determined while interacting with a tyrosine-containing peptide derived from a receptor. As such, this study is also an example of the use of NMR to study the interactions between molecules. The three-dimensional NMR experiment was coupled with heteronuclear techniques to increase the level of resolution of the spectra. For larger proteins such as IRS-1, homonuclear experiments are limited because proton resonances become broader, and the efficiency of magnetization transfer between protons is decreased.

With the advent of recombinant DNA technology, this problem can be overcome by producing the proteins to contain isotopic labels, such as ^{13}C , ^{15}N or ^2H , either at specific sites or uniformly throughout the protein. The magnetic properties of these nuclei offer significant advantages over protons. Carbon and nitrogen nuclei resonate over a much larger spectral width or range of frequencies, and as such are less likely to suffer from overlap. Also their scalar couplings to each other and to protons are higher in magnitude, and a more efficient magnetization transfer takes place than for ^1H - ^1H couplings. Thus, for macromolecules, heteronuclear experiments that correlate ^{15}N to ^{13}C nuclei or to protons offer significant gains in sensitivity and resolution compared to homonuclear experiments. The most often used heteronuclear experiments are the heteronuclear single quantum coherence experiment (HSQC) and the related heteronuclear multiple quantum coherence experiment. These experiments allow the measurement of one- and two-bond heteronuclear couplings (and homonuclear ^{13}C - ^{13}C couplings). They are most often combined with traditional two-dimensional experiments such as NOESY and TOCSY to yield a three-dimensional experiment. For example, in the case of an HSQC-NOESY spectrum of a protein, two of the axes represent the heteronuclei such as ^{15}N and the protons which are directly attached to the nitrogen nuclei, while the third axis contains chemical shifts of protons which share an NOE effect with the amide proton. This offers a significant increase in resolution compared to a traditional two-dimensional NOESY. A large array of these types of three-dimensional, heteronuclear-edited experiments have been designed to extract structural information in various situations, and are described in other articles in this encyclopedia.

Using these methods, the structure of the PTB domain of the IRS-1 protein was found to be similar to phosphopeptide-binding regions of several other proteins. Once the structural details were known, the different binding specificities could be compared and rationalized based on the interactions with their substrates.

Drug Interactions with Macromolecular Targets

NMR spectra are capable of supplying information about molecular interactions in solution. When a drug interacts with a receptor in a reversible manner, a number of effects may be observed in the spectra due to the exchange of the molecules between free and bound states. These effects will be discussed in relation to studies of anti-tumour antibiotics binding to short sequences of oligonucleotides. Compounds such as adriamycin (**Figure 7**) are currently in use as chemotherapeutic agents, and an understanding of factors involved in binding specificity may lead to more effective drugs to combat cancer.

Figure 7 Chemical structures of intercalating and minor groove DNA binding ligands.

Chemical exchange effects have been exploited to great effect in obtaining information about these interactions.

The free and bound states of the molecules represent two different chemical environments in which participating molecules may be found. Thus, the same nucleus of a particular molecule may be characterized by different values for NMR parameters, such as chemical shift, when located in each different environment and may give rise to different sets of resonances. The ability to measure the parameters that characterize each environment is dependent on the rate at which the nucleus exchanges between them. The exchange rate therefore has a significant effect on the appearance of NMR spectra, and the exchange rate is dependent upon the affinity of the drug for the receptor. The kinetics of the interaction can be examined by acquiring a series of spectra in which the concentrations of the reactants or the temperature are modulated.

Figure 8 shows an expansion of the aromatic region of a series of ^1H NMR spectra of the oligonucleotide duplex $d(\text{GGTAATTACC})_2$ to which has been added increasing amounts of a terephthalamide derivative (**Figure 7**). It is clear that the addition of the ligand causes significant perturbations of the free DNA resonances, and these indicate that the molecules are interacting. At ligand:DNA ratios between 0:1 and 1:1

Figure 8 Expanded aromatic regions from the 300 MHz ^1H NMR spectra of complexes between a terephthalamide derivative and $\text{d}(\text{GGTAATTACC})_2$, recorded at 10°C . Increasing ligand concentrations cause perturbations to chemical shifts of nuclei located at or near the binding site. All perturbations are upfield except for adenine H2 resonances that are perturbed downfield and are located on the floor of the minor groove.

there is a mixture of DNA molecules that are bound and unbound. The DNA resonances observed are averages of resonances arising from each of these states, and this is characteristic of fast exchange between the bound and unbound state due to a low affinity of the ligand for the binding site. There is a point in the titration in which the DNA resonances are no longer perturbed, and this identifies the point at which all binding sites have been occupied and there are only bound DNA molecules present in solution. By noting the resonances that are most perturbed and the direction of the perturbation (upfield or downfield), it was determined that the ligand was bound at the 'ATTA' binding site. The observed perturbations were consistent with the ligand being inserted edge-on into the minor groove. This places protons on the floor of the groove in the same plane as the aromatic drug which are then deshielded due to ring current effects. Protons above and below the plane of the ring experience shielding ring current effects.

An example of a ligand that has a high affinity for the binding site and exhibits slow exchange characteristics is shown in **Figure 9**, where the antitumour antibiotic hedamycin (see **Figure 7**) was titrated into a solution of the oligonucleotide duplex $\text{d}(\text{CACGTG})_2$. Upon addition of hedamycin, the free DNA resonances diminish in intensity and new peaks appear in the spectrum. These new peaks do not correspond to chemical shifts of the free duplex or ligand resonances and increase in intensity

Figure 9 Expanded regions from the 300 MHz ^1H NMR spectra of complexes between hedamycin and $\text{d}(\text{CACGTG})_2$, showing (a) aromatic resonances and (b) methyl resonances. Spectra up to 0.8:1 ligand:DNA ratio were recorded at 2°C and the complex allowed to equilibrate for 24 h at this temperature. Subsequent spectra were recorded to 10°C as the resonances were sharper. The dotted arrows highlight resonances that disappear after the 24 h equilibration period.

with increasing ligand concentration. This suggests that they arise from the bound form of these molecules, and that slow exchange conditions exist due to the high affinity of the ligand for the binding site. In this particular case it became apparent that time-dependent changes in the spectra were taking place. Allowing the mixture to equilibrate for 24 h resulted in certain resonances disappearing from the spectrum and sharpening of the remainder of the resonances. Given that hedamycin was subsequently shown to intercalate and alkylate, the transient peaks may represent reaction intermediates prior to alkylation where the ligand is intercalating reversibly to sites other than the most favoured binding site, and the sharpening of the spectra is caused by alkylation of the DNA by the ligand.

In cases where the binding affinity is high, or the binding is irreversible, a detailed model of the interaction between the molecules can be constructed based on intermolecular NOEs. A NOESY spectrum of the 1:1 complex of hedamycin with $\text{d}(\text{CACGTG})_2$ is shown in **Figure 10**. Assignment of the resonances was achieved using a combination of COSY, TOCSY and NOESY

Figure 10 Contour plot of the 500 MHz ^1H NOESY spectrum of the 1:1 hedamycin:DNA complex recorded at 10°C with a mixing time of 300 ms. Spectra were acquired on a Bruker 500AMX spectrometer with 2048 complex data points in the t_2 dimension and a total of 512 free induction decays (FID) collected for transformation in the t_1 dimension. Each FID was acquired with a total of 128 scans.

spectra. As in the case of proteins, the NOESY spectra of oligonucleotides yield characteristic crosspeak patterns that allow the sequential assignment of residues. Once the spectrum had been assigned and intramolecular NOEs arising from the DNA duplex and hedamycin had been eliminated, a total of 61 intermolecular NOEs from each of the oligonucleotide strands to protons located on the chromophore, epoxide chain and sugar groups of hedamycin were identified. These intermolecular NOEs identified the binding site and allowed the orientation of the ligand within the binding site to be determined.

For example, a number of intermolecular NOEs, summarized in **Figure 11**, showed that the molecule was intercalated between the central CG basepairs. Similarly, intermolecular contacts showed that the sugar groups of the molecule were located in the minor groove (**Figure 12**) and the epoxide chain in the major groove. Furthermore, the epoxide chain was shown to be in an appropriate location, so that the terminal carbon was capable of alkylating to the N7 of the guanine. Direct evidence for this was observed in that the guanine H8 proton became labile (i.e. disappeared when spectra were acquired in D_2O) following complexation.

Another example involving proteins is the interaction of the PTB domain of the IRS-1 protein with a tyrosine phosphorylated peptide in which the peptide was found to bind in a surface-exposed pocket of the PTB domain. More specifically, the peptide was bound along one

Figure 11 Schematic representation of NOEs observed between the central GC basepairs and the hedamycin ligand. Contacts to major groove protons are shown as dotted arrows and contacts to the minor groove are shown as solid arrows.

strand of the β sheet structure of the PTB domain and interacted with an α helix. Hydrogen bonding, van der Waals contacts and hydrophobic interactions stabilized the interaction. The peptide was found to be in a type I β turn, and the N-terminal residues of the peptide were in an extended conformation that formed an additional strand of the PTB domains β sheet.

Combinatorial Methods

Traditional methods of drug discovery involved a search amongst a range of diverse compounds that were ultimately derived from nature. This was a long and arduous process in which advances were due more often to serendipity rather than scientific thought and technique. The means to study the three-dimensional conformation of drugs and their receptors opened the door to a more rational approach in which compounds could be synthesized to better interact with a receptor. Along with the better understanding of drug/receptor interactions came improvements in biochemical techniques to isolate receptors and test compounds for their affinity towards these receptors. The ability to test thousands of compounds in a relatively short amount of time using high throughput

Figure 12 Schematic representation of contacts between the sugar rings of hedamycin and the DNA duplex. Contacts are observed only to minor groove protons and each ring is associated predominately with one DNA strand.

screening methods resulted in pressure to produce large numbers of diverse compounds to be tested.

Analysis of Solid-State Intermediates

Combinatorial chemistry is a term used to describe the production of a large number (thousands) of diverse compounds, and different methods are employed to achieve this. One such method is solid-phase synthesis where the chemistry occurs on a solid support that may be packed into a column. The solid support may be a material such as crosslinked polystyrene and the compounds to be produced generally consist of a number of basic pharmacologically relevant structures (pharmacophores) that are to be linked in different ways. The method requires that one of the pharmacophores be linked to the solid support, then each subsequent pharmacophore can be delivered to the column with appropriate reagents, allowed to react, and then washed off the column. By varying the order in which the pharmacophores are delivered, different compounds can be produced.

This method relies heavily on the use of NMR to assess the success of each reaction step. As a non-destructive technique, a sample of the resin may be removed, placed in

the NMR machine and then returned to the column. However, the fact that the compound is attached to the resin results in broad resonances if solution NMR techniques are utilized. This difficulty is circumvented by using solid-state NMR methods, including magic angle spinning (MAS). These experiments lead to narrow linewidths and high quality spectra, so that even two-dimensional experiments can be performed.

Combinatorial Methods in Drug Discovery

One of the most interesting applications of NMR in drug research is in the field of high throughput screening. One such described approach bridges combinatorial chemistry with biochemical screening and was named 'SAR by NMR'. The first step in this method is to identify the ability of ligands to bind to a target preparation of the molecular therapeutic target (e.g. an enzyme) in solution. Thus, batches of ligand mixtures (e.g. one batch containing 20 compounds) are allowed to interact with the enzyme preparation in solution while following changes in the protein ^{15}N and ^1H NMR frequencies.

In this manner, batches that produce a response can be identified quickly and the compounds within each batch further tested to identify specific compounds that bind to adjacent but different sites on the protein. These ligands are then further optimized using rational design techniques to improve the binding at each respective site. The second generation ligands are then linked together to produce a compound that has a higher affinity than either of the two lead compounds. Using this method it was possible to identify two ligands that bound with micromolar affinities to the FK506 binding protein, which is involved in immunosuppression when activated. Linking these two individual ligands resulted in a compound that bound to FK506 binding protein with a nanomolar affinity. Variations of this technique, which is applicable only to biomolecules of less than 30 kDa, indicates that it can have wide-ranging usefulness and is a potentially valuable tool in drug research.

Symbols

a, b, c	lattice vectors defining unit cell
a_i^*	length of i th reciprocal lattice vector
C_j	j th calculated model quantity, either $ F_{\text{calc}}(h, k, l) $ or $ F_{\text{calc}}(h, k, l) ^2$
D	deviance, distance criterion in model fitting
d_{calc}	calculated interatomic distance
d_{obs}	observed interatomic distance
f_n	atomic scattering factor of n th atom
$F(h, k, l)$	structure factor with Miller indices h, k, l
$ F(h, k, l) $	structure amplitude with Miller indices h, k, l
$ F_{\text{calc}}(h, k, l) $	calculated structure amplitude on relative scale
$ F_{\text{obs}}(h, k, l) $	observed structure amplitude on relative scale
h, k, l	Miller indices
i	square root of -1
$I(h, k, l)$	intensity of Bragg reflection
J	number of observations
K	scaling factor
k	index of k th refinement interaction (e.g., $p^{(k)}_m$)
L	maximum likelihood function
L_p	Lorentz-polarization correction
M	number of adjustable parameters
N	normal matrix with elements $N_{m,n}$
O_j	j th observed quantity, either $ F_{\text{obs}}(h, k, l) $ or $ F_{\text{obs}}(h, k, l) ^2$
p_m	m th adjustable parameter
p_n	site occupancy factor of n th atom
$R1$	reliability index with respect to $ F(h, k, l) $
$wR2$	weighted reliability index with respect to $ F(h, k, l) ^2$
S	goodness-of-fit, $S = \{D/(J - M)\}^{1/2}$
TLS	rigid-body thermal displacement description
T	transmission factor or Debye–Waller factor
T_n	Debye–Waller factor of n th atom
u	standard uncertainty

$U^{i,j}$	anisotropic atomic displacement tensor element
v	vector of normal equations with elements v_m
w_j	weight of j th observation
x_n, y_n, z_n	positional coordinates of n th atom
y	extinction correction
φ	logarithm of probability density function
$\rho(\zeta)$	probability density function
σ	standard deviation, square root of variance measure for width
ζ	random variable with mean 0.0 and variance 1.0

Crystallographic structure refinement is generally understood to be the last step in the determination of a crystal structure by diffraction methods. The usual procedure of a crystal structure analysis includes collection of X-ray or neutron diffraction intensities, data reduction yielding structure factor amplitudes, solution of the crystallographic phase problem yielding approximate structural parameters, and finally refinement of these parameters to obtain the best fit of the observed structure factor amplitudes with the amplitudes calculated from the optimized model. The methods used to accomplish these successive steps depend on the type of compound and crystal. It is convenient to distinguish between small structures containing up to 100 or 200 symmetrically independent atoms, and macromolecular structures. The former are solved with atomic resolution, often routinely and nearly automatically, using standard and well-tested program packages. Modern efficient data collection apparatus employing area detectors and adequate computing power have enabled small-molecule crystallography to become an analytical technique with turnaround times measured in days or even fractions of a day. Complete small-molecule structure determinations are normally carried out on single-crystal data, but the number of successful structure solutions from synchrotron powder diffraction data is steadily increasing. The methodology applied to macromolecular structures has evolved quite independently. Corresponding software packages and algorithms are distinct

to a large extent from those applied to small structures, but small-molecule crystallography has started to incorporate some of the techniques applied to macromolecules and the dialogue is open. The present article is devoted mainly to methods of small-molecule structure refinement against single-crystal diffraction data, offered by widely distributed program packages such as SHELX-97, CRYSTALS, XTAL and applied to chemical crystallography.

Model Fitting

The interpretation of measured quantities using a model derived from theory is a universal process in the physical sciences. The model is expressed by mathematical equations and contains constant numbers and parameters whose values are not fixed by the theory. The aim is then to find values for these variable parameters that best reproduce the observed quantities. The quality of the fit is judged according to a criterion that defines the distance between observed and modeled quantities. Model fitting is thus equivalent to the minimization of a multiparameter function expressing a distance criterion. Observations are always carried out to a limited precision, characterized by the standard uncertainty akin to the standard deviation or square root of the variance of a statistically distributed quantity. An important question to be answered is then the derivation of the standard uncertainties of the adjusted parameters of the model. This question is complicated by the fact that models are invariably imperfect: since they are obeyed only approximately, they cannot in principle obtain a perfect fit even for perfectly precise data. A crystallographic example is the use, in all models, of the kinematic scattering theory, which is correct only in the limiting case of vanishing diffracted intensity. Such model deficiencies are often referred to as 'systematic errors'. They may be reduced by performing experiments more closely related to the theoretical model. A further problem derives from applying corrections to the observations. Thus, observed diffraction intensities are corrected for background scattering, Lorentz and polarization factors, and absorption effects. The resulting pseudo-observations (squared structure amplitudes on a relative scale) are then used as observations in the model fitting. Their values are in general correlated since an uncertainty in a correction and also systematic errors will affect all of them. This correlation is neglected in nearly all refinement software.

The Crystallographic Model

The standard *procrystal model* assumes that the electron distribution in the crystal is very nearly equal to a superposition of previously known rigid atomic density distributions, which are smeared by harmonic lattice vibrations. The structure factor $F(b, k, l)$ with integer Miller

indices b, k, l for n atoms per unit cell, located at the positions x_m, y_m, z_m , then becomes

$$F(b, k, l) = \sum_{n=1}^N p_n f_n T_n \exp[2\pi i(bx_n + ky_n + lz_n)] \quad [1]$$

The atomic scattering factors f_n are the Fourier transforms of the spherical atomic electron distributions. They are considered as known from quantum-chemical calculations. The site-occupation parameters p_n may assume values different from unity if the structure is disordered. The Debye-Waller factors T_n allow for the atomic thermal motions. They are functions of the atomic displacement parameters $U^{i,j}$. Omitting the atom index n and representing the Miller indices and lengths of the reciprocal lattice vectors by b_i and a_i^* , respectively:

$$T = \exp \left[-2\pi^2 \sum_{i,j} U^{i,j} a_i^* a_j^* b_i b_j \right] \quad [2]$$

There results nine adjustable parameters per atom, i.e., three positional coordinates and six displacement parameters, and sometimes an additional site-occupation parameter, although the point symmetry of an atom in a special position may reduce the number of adjustable parameters. The model value of the net intensity $I(b, k, l)$, Bragg peak minus background, is

$$I(b, k, l) = K \text{Lp } T \gamma |F(b, k, l)|^2 \quad [3]$$

where K is a scale factor, Lp the Lorentz-polarization correction, T the transmission factor allowing for X-ray absorption, and γ an extinction correction allowing for some deficiencies in the kinematic scattering theory. The observed net intensities are routinely corrected for Lp and somewhat less routinely for T . The resulting corrected observations $|F_{\text{obs}}|^2$ and the corresponding model quantities $|F_{\text{calc}}|^2$ thus become

$$|F_{\text{obs}}(b, k, l)|^2 \rightarrow K \gamma |F(b, k, l)|^2 - |F_{\text{calc}}(b, k, l)|^2 \quad [4]$$

where γ depends on one or more parameters, and K is also adjustable. Taking the square root of both sides gives the model in terms of structure amplitudes $|F|$. Each observed quantity is accompanied by an estimation of its uncertainty, usually derived from counting statistics and the spread of multiple and symmetry-equivalent observations around their average value. The model may of course be augmented at will by additional parameters (twinning ratios, enantiomorph-polarity parameter, charge density or anharmonic motion parameters, etc.), but these are included in every refinement software.

The Principle of Least Squares

By far the most important distance criterion between observed and modeled quantities is the least-squares deviance

$$D = \sum_{b,k,l} w(b,k,l) \{ |F_{\text{obs}}(b,k,l)|^2 - |F_{\text{calc}}(b,k,l)|^2 \}^2 \quad [5]$$

or analogously in terms of $|F|$, $w(b,k,l)$ being a weighting factor. The problem of structure determination, including the crystallographic phase problem, is thereby formulated in terms of an optimization criterion: find the minimal deviance D by varying all the parameters of the model defined by eqns [1], [2], and [4]. The solution would be unique and could be easily obtained if the equations for $|F_{\text{calc}}(b,k,l)|^2$ describing the model were linear. However, they are highly nonlinear and a unique solution is not assured (although solutions of ordered structures at atomic resolution are indeed most probably unique). The optimization for nonlinear model equations becomes an iterative process, starting with approximate parameter values obtained by the methods of structure determination. For this reason, the structure solution and the structure refinement steps are usually dealt with separately.

In the following, the M variable parameters of a structure are denoted by p_m ($1 \leq m \leq M$), the J observations $|F_{\text{obs}}(b,k,l)|^2$ or $|F_{\text{obs}}(b,k,l)|$ by O_j ($1 \leq j \leq J$), and the corresponding model quantities by C_j . The usual iterative Gauss–Newton method for approaching the optimal value of D , starting from approximate values $p_m^{(k)}$ for the adjustable parameters obtained in the (k) th iteration, is to linearize the model equations for C_j . The deviance D (see eqn [5]) to be minimized with the improved parameter values $p_m^{(k+1)}$ then becomes

$$D = \sum_{j=1}^J w_j \{ O_j - C_j[p_1^{(k+1)} \dots p_M^{(k+1)}] \}^2 \quad [6]$$

$$C_j[p_1^{(k+1)} \dots p_M^{(k+1)}] \approx C_j[p_1^{(k)} \dots p_M^{(k)}] + \sum_{m=1}^M \left(\frac{\partial C_j}{\partial p_m} \right)_k [p_m^{(k+1)} - p_m^{(k)}] \quad [7]$$

The partial derivatives are evaluated with the parameters $p_m^{(k)}$. This leads to the matrix equation $N[p^{(k+1)} - p^{(k)}] = \mathbf{v}$ with elements $N_{m,n}$ of the *normal matrix* N and v_m of the vector $\mathbf{v}$:

$$N_{m,n} = \sum_{j=1}^J w_j \left(\frac{\partial C_j}{\partial p_m} \right)_k \left(\frac{\partial C_j}{\partial p_n} \right)_k \quad [8]$$

$$v_m = \sum_{j=1}^J w_j [O_j - C_j^{(k)}] \left(\frac{\partial C_j}{\partial p_m} \right)_k$$

The process starts with the parameters $p_m^{(0)}$ obtained with the methods of structure solution. Algorithms for solving

eqn [8] are described in the literature. If the number of observations is much larger than the number of parameters, e.g., $J/M \approx 10$, and if the structure is well ordered, the diagonal terms $N_{m,m}$ are large compared to the off-diagonal terms, and N is easily invertible. A refinement may be started with the scale factor and the positional parameters. The displacement parameters are then found automatically starting from values with reasonable orders of magnitude or from zero, and convergence is rapid. However, the observations may not be particularly sensitive to certain structural features of interest. The normal matrix then risks being nearly singular, the results of matrix inversion may be dominated by rounding errors, and convergence of the iterative adjustment is not guaranteed and may be meaningless. Examples of ill-conditioned problems are the parameters of weakly scattering hydrogen atoms in the presence of heavy atoms, or those of split atoms in disordered structures. In such cases, experience shows that it is in the use of a more appropriate model, constraints, and restraints (see the following text), that refinement can be achieved rather than in resort to more advanced numerical algorithms.

The Gauss–Newton algorithm is not the only method capable of minimizing the deviance (eqn [5]). The deviance of ill-conditioned nonlinear least-squares problems may possess several, often shallow, minima. There is then no guarantee that the minimum found starting from a given trial structure is the lowest one. The method of *simulated annealing* may be suitable for such problems, as it allows a jump from a local minimum in search of another. It is frequently used in macromolecular crystallography.

Estimation of Uncertainty

A result of a measurement is not complete without a quantitative statement of its uncertainty. Likewise, the value of a quantity derived from the measurement must be accompanied by its uncertainty. The uncertainty reflects the lack of exact knowledge of the value owing to random and systematic effects including deficiencies in the model. The quantitative measure of uncertainty is called standard uncertainty. It is an estimate of the standard deviation σ (i.e., the positive square root of the variance) of the probability density function of the quantity.

The method of least squares allows standard uncertainties to be obtained for all adjusted parameters. For any weights w_j and for any probability density function of the observations, linear least squares is an unbiased estimator if the weights are independent of the observations, and if the model is perfect, i.e., represents physical reality correctly for some values of the parameters. In particular, the *Gauss–Markov theorem* states that minimal variances of the estimates are obtained if

the weights are chosen equal to the inverse variances of the observations, $w_j = \sigma_j^{-2}$. For these, and only for these weights, the inverse of the normal matrix N^{-1} is an unbiased estimate of the variance–covariance matrix of the model parameters. In particular, the square roots of the diagonal terms of N^{-1} are the standard uncertainties of the adjusted parameters. It has been tacitly assumed in the foregoing that the observations are statistically independent, i.e., that their covariances are zero. The Gauss–Markov theorem applies, in fact, also to correlated observations. Generally, valid expressions for the variance–covariance matrix of the model parameters for weights other than minimum-variance weights are rarely implemented in refinement software. As a rule, crystallographic software implements estimated minimum-variance weights, $w_j = u_j^{-2}$, where u_j is the standard uncertainty of O_j . The use of reliable values for these standard uncertainties is of utmost importance. They may be estimated from the spread of multiply measured or symmetry-equivalent Bragg intensities about their average values, the intensity fluctuations of periodically measured check reflections, and Poisson statistics of count rates. The latter may be estimated from the observed O_j , the model C_j , or a combination of these quantities. When other weights, e.g., unit weights, are used, the apparent standard uncertainties of the model parameters obtained from N^{-1} will be meaningless.

The goodness-of-fit S is a measure of the extent to which the calculated model values C_j agree with the observations O_j . For minimum-variance weights, S is calculated as

$$S^2 = (J - M)^{-1} D_{\min} = (J - M)^{-1} \sum_{j=1}^J u_j^{-2} (O_j - C_j)^2 \quad [9]$$

where $D_{\min}$ is the deviance at convergence, and u_j are the standard uncertainties of the O_j . J and M have been defined earlier. The expectation value of S for a perfect model is $\langle S \rangle = 1.0$. If the probability density functions of the observations are Gaussian, $D_{\min}$ is distributed like χ^2 with $J - M$ degrees of freedom. In practice, values for S near unity are rarely obtained even for fairly estimated u_j values. Apart from the possibility of inappropriate measurement procedures, this is explained by imperfections in the model: for example, the standard procrystal model neglects the effects of chemical bonding and anharmonic thermal motions, the kinematic theory of diffraction may be a questionable approximation to reality, and X-ray absorption effects may have been incompletely accounted for. It is a common practice among crystallographers to multiply the standard uncertainties of the parameters obtained from N^{-1} by S . Although this is equivalent to the unrealistic assumption that a lack of fit is due entirely to a constantly proportional underestimation of the standard uncertainties of the observations, it does have the advantage of increasing the

standard uncertainties of the parameters obtained from N^{-1} . Moreover, other elaborate schemes of uncertainty manipulation are in use for attaining $S \approx 1$.

It may be important to stress at this point that standard uncertainties of parameters optimized with crystallographic programs depend on the method of refinement. Thus, if a parameter has been fixed because it was highly correlated with another parameter, thereby leading to an ill-conditioned normal matrix, the resulting standard uncertainties refer to an effective model where the fixed parameter assumes its true value that is previously known. Adjusting correlated parameters by alternately fixing one at its current value while refining the other is an unacceptable practice: it masks the fact that the parameters may not be obtainable from the available data, and their standard uncertainties will be severely underestimated. Another example is block-diagonal refinement: to save storage space and computer time, the normal matrix is decomposed into a set of smaller matrices by neglecting off-diagonal terms outside the latter. With increasing computer power, this practice has been progressively abandoned but may still be attractive for large structures. The resulting standard uncertainties may, however, be underestimated, particularly if one or more of the neglected matrix elements assume large values. Wherever possible, the standard uncertainties should be calculated from an unrestricted full normal matrix.

Maximum Likelihood

Maximum likelihood is a more general statement of the optimization problem than least squares. Instead of optimizing a distance criterion such as the deviance D , the problem may be stated in the following manner: ‘Given a model and a set of observations, what is the likelihood of observing those particular values, and for what values of the parameters of the model is that likelihood a maximum?’ The answer depends on the probability density functions ρ of the observations O_j . Assuming the observations to be uncorrelated and the model quantities C_j to be the expectation values of the O_j , the probability of observing the set of the O_j is the likelihood L ,

$$L(p_1 \cdots p_M) = \prod_{j=1}^J \rho[O_j - C_j(p_1 \cdots p_M)] \quad [10]$$

L , or more easily the logarithm $\ln L$, is maximized by varying the parameters p_m . Simple algebra gives for the gradient of $\ln L$:

$$\frac{\partial \ln L}{\partial p_m} = (1/2) \sum_{j=1}^J \left[\frac{\zeta_j^{-1} d\phi(\zeta_j)}{d\zeta_j} \right] \left[\frac{\partial \zeta_j^2}{\partial p_m} \right] \quad [11]$$

$$\phi(\zeta_j) = \ln \rho(\zeta_j); \zeta_j = \frac{(O_j - C_j)}{\sigma_j}$$

where σ_j is the square root of the variance of the function $\rho(\zeta_j)$, or a measure for the width of $\rho(\zeta_j)$. The term $\partial \zeta_j^2 / \partial p_m$ is the gradient of eqn [6] with $w_j = \sigma_j^{-2}$. For a Gaussian function, $\rho(\zeta) = (2\pi\sigma^2)^{-1/2} \exp(-\zeta^2/2)$, maximum likelihood is identical with minimum-variance least squares. If $\rho(\zeta)$ is not Gaussian, eqn [11] shows that maximum likelihood is equivalent to minimizing a least-squares deviance, where the minimum-variance weights are multiplied after each cycle by a function of the current deviates $O_j - C_j$. For a Cauchy function, $\sigma(\zeta) = \pi\sigma(1 + \zeta^2)^{-1}$, the modified weights are $w_j = [\sigma_j^2 + (O_j - C_j)^2]^{-1}$. Strongly discordant data are thus down-weighted because they are much more probable for a Cauchy function than for a Gaussian.

The probability density functions of the observations are generally unknown, but the Gauss–Markov theorem ensures that least squares is always an acceptable estimator. However, the results of least squares are strongly influenced by discordant observations, so-called outliers. The *robust-resistant* techniques use weight-modification functions of $O_j - C_j$, which progressively down-weight outliers. These functions implicitly define probability functions ρ . They may alternatively be interpreted as an appreciation of the reliability of certain measurements. This approaches the frequently used option to simply omit discordant observations because they are judged to be unreliable.

Constraints

It is usually necessary, and often desirable, to impose relations between the parameters of a model. The problem to be solved is then a minimization of eqn [6] while imposing subsidiary conditions. A constraint satisfies such a condition exactly. A *restraint* (soft constraint) is a condition accompanied by a measure of uncertainty or a weight, and accordingly satisfies the condition only approximately.

Most crystallographic refinements require parameter constraints due to site symmetries. For example, the position of an atom on a mirror plane is defined by two independent coordinates only. The displacement tensor of such an atom is defined by four, rather than six, $U^{i,j}$ values, since one of its eigenvectors must be perpendicular to the plane. Modern refinement programs find and apply such constraints automatically for all possible site symmetries. In some space groups, the origin of the coordinate system cannot be fixed with respect to the symmetry elements and thus must be defined by a constraint between positional parameters. Certain programs detect this condition and apply the constraint automatically; others do not. If site-occupation parameters are refined, a constraint assuring electro-neutrality may be required. The above-mentioned types of constraint are usually implemented in the software by the method of parameter elimination.

Certain special features to be imposed on a model may be expressed by more complicated constraint equations. Note as an example the assumption of a rigid molecule with prescribed dimensions whose position and orientation are to be refined. The position may be described by the coordinates of the center of mass and the orientation by three Euler angles with respect to a unitary coordinate system. The atomic coordinates and thus the structure factor, eqn [1], are expressed as functions of these six parameters. The latter may then be adjusted to optimize the deviance. A similar procedure can be used to constrain the atomic displacement parameters of a molecule to rigid-body movements described by a translation tensor, a libration tensor, and a translation/libration-correlation tensor (TLS model). This model neglects intramolecular vibrations.

Restraints

Restraints are used to specify certain features of the structural model that are approximately known. For example, typical values of the bond lengths such as C–C or C–H are well known; the quality of a structure determination is indeed judged by, among other properties, the plausibility of bond lengths. Bond lengths in well-ordered small-molecule structures are, as a rule, accurately determined from the diffraction data. This is not the case for those macromolecular structure determinations that do not attain atomic resolution. It may not be the case for disordered structures characterized by split-atom positions and superpositions of molecules or structural fragments in various orientations, such as found in the structures of fullerenes, C_{60} and C_{70} , or in structures containing highly symmetric ions such as ClO_4^- . Powder diagrams may also contain insufficient information for the determination of all atomic positions. In such cases, the prior knowledge of bond lengths may permit a successful structure refinement.

Bond lengths are not known with absolute precision, nor does a bond between two atoms assume exactly the same value in all structures. Bond lengths should, therefore, not be fixed to a particular value by a constraint. Instead, they are introduced in the form of additional observational equations. The distance between atoms m and n is

$$d_{\text{calc}} = |(x_m - x_n)\mathbf{a} + (y_m - y_n)\mathbf{b} + (z_m - z_n)\mathbf{c}| \approx d_{\text{obs}} \quad [12]$$

where d_{obs} has an associated standard uncertainty u expressing the confidence to be placed in this information. This pseudo-observation is used, like all other observations, in eqns [6], [7], and [8], with a weight $w = u^{-2}$. A residual $|d_{\text{obs}} - d_{\text{calc}}|$ of the order of u shows the distance information to be useful. A large residual,

however, indicates a contradiction between distance and diffraction information, which must be taken seriously: one of the two types of information or the corresponding weights may be erroneous. Simply increasing the weight of the restraint equation at the expense of the observations may be the most inadequate, even if it leads to a closer agreement of the bond length with its expectation.

Other geometrical restraints may be applied to bond angles and torsion angles. Groups of atoms may be restrained to occupy a plane by fixing one or several torsion angles to be 0° or 180° . *Similarity restraints* are used to impose two or more bonds to be of the same length without specifying the value of the bond length. This permits the restraint of the hexagonal symmetry of a phenyl ring, or the icosahedral symmetry of a C_{60} molecule. Restraints are thus far more flexible than rigid-molecule constraints, and may be applied to only part of a molecule. Distance and angle information alone, without diffraction data, has been used to optimize atomic coordinates in framework structures. Examples are refinements of aluminosilicate frameworks in zeolites starting with unit cell data as determined from powder diagrams, and assuming diverse space groups belonging to subgroups of the holohedral lattice symmetry (the highest symmetry compatible with the metric of the translation lattice).

The vibrationally rigid-bond criterion expresses the expectation that the amplitudes of intramolecular vibrations should be much smaller than those of the translational and librational movements of a molecule. The mean-square displacements of two strongly bonded atoms along their bond should accordingly be approximately equal. Accurate structure determinations confirm this criterion for C–C bonds, but not for metal–ligand bonds in transition-metal complexes. Vibrationally rigid bonds may be imposed by rigid-bond restraints on the anisotropic displacement parameters. If all interatomic distances in a molecule are specified to be rigid, its thermal motions are restrained to rigid-body translation and libration (TLS), except if the molecule is linear or planar. With respect to a constrained TLS-refinement mentioned earlier, restraints offer the advantage that partially rigid molecules or structural groups may be defined.

Shift-limiting restraints are used to improve the convergence of iterative least-squares cycles. Strongly correlated parameters, such as displacement and site-occupation parameters refined against a low-resolution data set, result in an ill-conditioned pseudosingular normal matrix. The minimum of the deviance with respect to such parameters may be very shallow, successive shifts may erratically oscillate in opposite directions, or the refinement may diverge. A shift-limiting restraint ensures that the shift of the parameter value is of the order of the associated uncertainty u , or in terms of eqn [7] $p_m^{(k+1)} - p_m^{(k)} \approx 0$ with weight $w = u^{-2}$.

Such a restraint simply adds w to the corresponding diagonal term of the normal matrix. This clearly leads to a better conditioned and more easily invertible matrix. After convergence, all shift-limiting restraints should be removed and a final cycle should be calculated to obtain acceptable standard uncertainties for the parameters. Shift-limiting restraints are a simplified version of the *Levenberg–Marquardt method* in which the diagonal terms of the normal matrix are multiplied by a number that approaches 1.0 at convergence.

In general, any function of the structural parameters may serve as a restraint. An important example in macromolecular crystallography is *molecular dynamics*. In addition to the diffraction data, an empirical potential energy expression E_{pot} is minimized, which contains terms for bond lengths, bond angles, torsion angles, and nonbonded interactions. The function minimized is then the sum of the deviance, eqn [5], and the energy, $D + E_{\text{pot}}$. Molecular dynamics is a generalization of the distance and angle restraints discussed earlier where the weights are derived from the expression for the energy.

Judging the results

The quality of the fit between observed and calculated structure amplitudes is commonly characterized by the agreement factors:

$$R1 = \frac{\sum_{h,k,l} ||F_{\text{obs}}| - |F_{\text{calc}}||}{\sum_{h,k,l} |F_{\text{obs}}|} \quad [13]$$

$$wR2 = \left\{ \frac{\sum_{h,k,l} w(|F_{\text{obs}}|^2 - |F_{\text{calc}}|^2)^2}{\sum_{h,k,l} w|F_{\text{obs}}|^4} \right\}^{1/2} \quad [13]$$

The conventional index $R1$ usually includes only the stronger reflections; a common selection is $|F_{\text{obs}}| > 4u_F$ or $|F_{\text{obs}}|^2 > 2u_{F2}$, where u_F and u_{F2} are the standard uncertainties of $|F_{\text{obs}}|$ and $|F_{\text{obs}}|^2$, respectively. The goodness-of-fit S defined by eqn [9] is a less appropriate measure, since some software adjusts the weights to bring this value close to 1.0. Values of $R1$ up to 0.07 are considered to be acceptable; for very accurate studies, all agreement factors are of the order of 0.02 or lower.

The optimal values of the parameters and their associated standard uncertainties are meaningful only in relation to the model employed in the final least-squares cycle. All constraints and restraints used should be reported. Note that the positions and displacement parameters of hydrogen atoms are often derived from the parameters of the heavier atoms and subsequently suitably restrained or constrained; corresponding bond lengths, such as C–H, are then features of the model and not experimental evidence.

In the final cycle, the best estimate of minimum-variance weights, $w = u^{-2}$, should be used, where $u = u_{F2}$ or u_F for refinements against $|F|^2$ or $|F|$, respectively.

The standard uncertainties of the refined parameters obtained from the inverse normal matrix are meaningful only if the standard uncertainties of the observations are meaningful. It should also be borne in mind that even in careful studies, model errors are unavoidable. These include imperfect corrections for absorption and extinction, as well as the standard procrystal approximation neglecting chemical bonding and anharmonic motions. In addition, the uncertainties of molecular parameters such as bond lengths are often computed neglecting correlations between the model parameters. Therefore, published uncertainties of refinement results are approximate and tend to be underestimates. They can be improved only through a careful estimation of μ_{F2} or μ_F and a reduction of model errors.

Analytical tandem mass spectrometry (MS/MS) relies on the ability to activate and dissociate ions in order to

identify or obtain structural information about an unknown compound. The most common means of ion activation in tandem mass spectrometry is collision-induced dissociation (CID). CID uses gas phase collisions between the ion and a neutral target gas to cause internal excitation of the ion and subsequent dissociation. Surface-induced dissociation (SID) is analogous to the CID experiment except a surface is substituted for the collision gas as shown in **Figure 1**. SID offers several advantages as a means of ion activation in tandem mass spectrometry, including fine control of the internal energy deposition, efficient translational to vibrational energy conversion, large average internal energy deposition, and applicability to both small organic and large biological molecules. Since

Figure 1 Simplified schematic of (a) a CID tandem mass spectrometer and (b) a SID tandem mass spectrometer where MS1 and MS2 are the mass analysers, M_1^+ is the parent or projectile ion, F_n^+ are fragment ions of M_1^+ generated in the ion source, and F_m^+ are fragment ions formed as a result of (a) CID and (b) SID.

1985, low energy polyatomic SID and its accompanying processes have been the subject of much research and continue to gain interest in the mass spectrometry community as an alternative means for ion activation, to study interesting ion/surface reactions, and to cause selective surface modification.

Low Energy Polyatomic Ion/Surface Collisions

When an ion collides with a surface, several processes may occur including elastic, inelastic, and reactive scattering or soft landing. **Table 1** lists possible events which occur for low energy polyatomic ion collisions with organic covered surfaces. Note that 'low energy' refers to the component of kinetic energy normal to the surface which is usually in the range of 1 to 100 eV. The parent or projectile ion, AB^+ , is accelerated (up to a few hundred eV) towards a substrate which has been chemically modified with an organic overlayer, Y, such as a self-assembled monolayer (SAM) surface (**Figure 2**). Since the projectile ion has a low normal component of collision energy, it interacts only with the outer layer of the adsorbate and not directly with the substrate. The ion will collide with the organic surface and may scatter from the surface without losing any kinetic energy. Generally, the polyatomic ion scatters from the surface with a loss of

kinetic energy which is distributed into internal energy of AB^+ and of the organic overlayer Y as described in the following equation,

$$Q = T - KE_{\text{final}} = V + \varepsilon_{\text{surface}} \quad [1]$$

where Q is the inelasticity of the collision event, T and KE_{final} are the initial and final kinetic energy of the projectile ion AB^+ , V is the total vibrational energy of the ion AB^+ , and $\varepsilon_{\text{surface}}$ is the internal energy deposited in the surface (radiative losses are ignored). If AB^+ becomes sufficiently activated, it will dissociate into fragment ions which are characteristic of the structure and chemical composition of the projectile ion.

Several processes are representative of reactive scattering, including neutralization, chemical sputtering, ion/surface reaction, and surface modification. Most reactive scattering processes occur through electron transfer from the surface to the ion. If no other processes occur after the electron transfer, then the only product formed is the neutralized projectile ion, AB, and no ions are detected. Chemical sputtering occurs when sufficient energy is deposited in the surface following the electron transfer and collision event causing adsorbate ions to be liberated from the surface. The incident ion or a fragment ion can incorporate an atom or group of atoms from the surface to form an ion/surface reaction product. Ion/surface reactions may also cause chemical modification of the adsorbate

<i>Soft landing</i> 	

through atom or molecule exchange reactions. One must distinguish between surface modifications that result from damage which occurs to an adsorbate during ion/surface collisions (for example, chemical sputtering) and a selective chemical modification that results from an ion/surface exchange reaction. Finally, specially chosen projectile ions can be soft landed into the adsorbate, specifically in fluorocarbon and hydrocarbon SAM surfaces, upon

collision at very low energies ($\sim 1\text{--}10\text{ eV}$). Remarkably, the deposited intact projectile ion remains in the surface as an ion protected by the adsorbate layer. This matrix-isolated ion has been shown to survive for several days in vacuum and a few days in ambient lab air.

Surface-Induced Dissociation Instrumentation

The fundamental requirement for performing an SID experiment is a tandem mass spectrometer. Several tandem mass spectrometers have been developed using various combinations of mass analysers and geometries to perform SID. **Table 2** lists several SID systems (by no means an exhaustive list), which have been organized by on-axis (or in-line) and off-axis geometry. On-axis geometry refers to a tandem mass spectrometer where the exit slit or aperture of the first mass analyser is in-line with the entrance slit or aperture of the second mass analyser. In the off-axis geometry, there is no common axis between the exit and the entrance of the first and second mass analyser. The on-axis and off-axis groups can be further divided into instrument collision geometry, that is, large incident angle/low collision energy and glancing incident angle/high collision energy. The incident angle is defined here as being referenced to the surface normal. Finally, a special group of mass spectrometers which trap ions have also been used to perform SID experiments. Quadrupole ion traps and Fourier transform ion cyclotron resonance mass spectrometers perform the tandem mass spectrometry experiment in a single mass analyser, i.e. the tandem mass spectrometry experiment is performed in one analyser with each MS

stage separated in time rather than separated in space as for a two-analyser system.

A simplified example of an SID tandem mass spectrometer is shown in **Figure 1b**. This system utilizes two mass analysers (MS1 and MS2) perpendicular to one another to mass select the projectile ion (MS1) and analyse the scattered product ions (MS2). Ions are generated in the ion source, accelerated, and focused into MS1 where the projectile ion, M_1^+ , is mass selected. M_1^+ is then further accelerated or decelerated (depending on the desired collision energy) and focused onto the surface. The product ions scattered from the surface are accelerated towards MS2 and the SID mass spectrum is then collected by scanning MS2 and measuring the ion current at the detector.

There are several design considerations which must be addressed when constructing an SID instrument, including vacuum conditions and instrument functionality. The first consideration is determining the vacuum requirement which will be sufficient for performing an SID experiment. For most SID instruments, the vacuum is typically in the range of 10^{-7} to 10^{-10} torr (1.3×10^{-5} to 1.3×10^{-8} Pa) and is dictated by the type of surface to be used in the experiment. If a clean and well-characterized single crystal is used as the SID target, then ultrahigh vacuum (UHV) conditions must be met ($<10^{-9}$ torr). For an organic covered surface, such as a self-assembled monolayer surface, less stringent vacuum conditions ($<10^{-6}$ torr) will suffice.

The type of ion source used in an SID experiment depends on the projectile ion under study. For instance, if volatile, small organic compounds are of interest then an electron ionization (EI) and/or chemical ionization (CI) source will be sufficient. However, if one wishes to study biological compounds then a spray or desorption ionization method will be required, such as electrospray (ESI), atmospheric pressure chemical ionization (APCI), desorption chemical ionization (DCI), or matrix-assisted laser desorption ionization (MALDI).

As seen in **Table 2**, several combinations of mass analysers have been used in SID instruments, each with their own advantages and disadvantages. The type(s) of mass analysers used in an SID system depends to some extent on the class of projectile ions to be studied, as with the method of ionization, but more so on the overall performance of the mass analyser. One must consider the resolution, sensitivity, size, ruggedness, ease-of-use, cost, and the compatibility of one mass analyser with another as well as the information sought in the SID spectra. The authors refer the reader to other articles in this text that discuss advantages and disadvantages of the various mass analysers.

The extent of fragmentation in an SID experiment is highly dependent on the component of kinetic energy normal to the surface. Thus, having control of the collision

energy (kinetic energy of the projectile) is necessary. The range of ion kinetic energy will depend on the collision geometry of the instrument. For example, if glancing incident angles are used then higher overall collision energies will be needed (hundreds of eV to keV), while more normal collisions will require a lower ion kinetic energy (1–100 eV). It has been shown that nearly identical SID spectra can be obtained from both glancing and large incident angle collisions as long as the component of kinetic energy normal to the surface is similar. While the angle of incidence is not that important analytically, subtle fundamental information can be obtained by controlling both the kinetic energy of the projectile and the angle of incidence. More fundamental information about the SID process and other ion/surface collision processes can be determined by measuring the energy of the scattered ions as well as their angular distribution. Hence, it is of interest to control the scattering angle independently of the incident angle and to have the ability to measure the kinetic energy of the scattered ions.

Surface science techniques are useful for monitoring changes in the structure and composition of the adsorbate before, during, and after ion/surface collisions. Common techniques include high resolution electron energy loss spectroscopy (HREELS), low energy electron diffraction (LEED), Auger electron spectroscopy (AES), secondary ion mass spectrometry (SIMS), reflection absorption infrared spectroscopy (RAIRS), X-ray photoelectron spectroscopy (XPS), and ultraviolet photoelectron spectroscopy (UPS). While little ion structural information is gained using these methods, changes in the adsorbate are of interest when studying ion/surface reactions, especially those which lead to surface modification.

A few examples of SID instruments are shown in **Figures 3 to 6** which incorporate some or all of the considerations discussed above. **Figure 3** is an off-axis large incident angle/low collision energy hybrid sector/quadrupole SID instrument of the BEEQ configuration (B = magnetic sector, E = electrostatic sector, and Q = quadrupole mass filter). This system has the ability to change the scattering angle independently of the incident angle, to measure the kinetic energy of the scattered product ions with the post-collision electrostatic sector, and to do traditional surface analysis in a separate UHV chamber. **Figure 4** presents the SIMION calculated ion trajectories for a custom-built, on-axis SID device used on a commercial four sector tandem mass spectrometer. (Dahl DA and Delmore JE (1989) *SIMION PC/PC2 version 4.02*, Idaho National Engineering Laboratory, EG and G Idaho Inc.) The mass analysed projectile ion beam enters from the left of the device, strikes a target, and the scattered ions are extracted to the right side of the device into the final mass analyser. The SID device can be used in two different modes including a single deflection and dual deflection mode. It is clear in the SIMION

Figure 3 Overview of a hybrid BEEQ tandem mass spectrometer. Reproduced with permission from Miller SA, PhD Thesis, Purdue University, 1997.

calculation that the dual deflection mode (Figure 4b and 4c) produces a more focused ion beam. An advantage of this SID system is that the SID device can be exchanged with a commercial CID device and direct comparisons of SID to high energy CID collisions can be observed. Figures 5 and 6 show two types of off-axis instruments that maintain large incident angle/low collision energy geometry but use different tandem mass analysers. The tandem time-of-flight system in Figure 5 has the ability to use several ionization techniques making it amenable to projectile ions ranging from small organics to large biological compounds. This system also employs delayed extraction technology to improve the resolution in the SID product ion mass spectra. A unique feature of the tandem quadrupole system in Figure 6 is that it is contained on a single 8" conflat flange and is easily attached to a standard UHV surface analysis system. Most currently used SID systems utilize off-axis large incidence angle/low collision energy geometry due to enhanced overall performance compared to on-axis systems.

Surface-Induced Dissociation

The characteristics associated with the SID process are listed in Table 3 and emphasize the analytical utility of SID as a method of ion activation. The first characteristic of SID listed in Table 3 is the ability to control the amount of fragmentation, or internal energy, by adjusting the collision energy. Figure 7 displays the SID mass spectrum resulting from the collision of p-methyl phenetole molecular ion with a fluorocarbon self-assembled monolayer (F-SAM) surface at two different collision energies. This example illustrates the effect that collision energy has on the extent of fragmentation. At a 15 eV collision energy, only the molecular ion and one fragment ion, m/z 108 (loss of C_2H_4), are observed. When the collision energy is increased to 30 eV, fragmentation occurs giving rise to a high energy fragment ion, m/z 29 ($C_2H_5^+$ and/or CHO^+) as the base peak and complete loss of the molecular ion at m/z 136. The fragment ions in Figure 7b are the same as those observed in the electron ionization mass spectrum of p-methyl phenetole but with different ion intensities.

A better fundamental understanding of the SID process is obtained by quantitating the partitioning of the transitional energy of the ion into internal energy of the ion, internal energy of the surface, and the kinetic energy of the scattered ions. In eqn [1], partitioning of the projectile kinetic energy in an ion/surface collision was described.

Rearranging this eqn to indicate energy conservation,

$$T = KE_{\text{final}} + V + \epsilon_{\text{surface}} \quad [2]$$

the ion transitional energy is the sum of the final kinetic energy of the scattered products, the total internal energy of the projectile ion and the energy absorbed by the surface. Despite the fact that experimentally determined values for KE_{final} and V are dependent on the nature of the surface and projectile ion, general conclusions can be made about the distribution of the projectile ion kinetic energy. For example, the kinetic energy of the scattered product ions represents a small fraction of T , typically less than 10%. The value obtained for V is approximately 10–30% and has been shown to be linear over a wide range of collision energies. The remaining energy, 60–80%, is absorbed by the surface.

Conversion of Ion Transitional Energy into Internal Energy ($T \rightarrow V$)

A quantitative variable used to judge the effectiveness of a collision ion activation technique is the translational to internal energy conversion efficiency or $T \rightarrow V\%$. The internal energy absorbed from a collision event is not single-valued, rather a distribution of internal energies is observed. Internal energy distributions can be measured using a thermometer molecule method which relies on a distinct set of dissociation pathways of known critical energy for a particular ion. The intensities of the fragment ions in the SID mass spectrum of the thermometer ion and the critical energies required to generate each fragment ion are used to calculate the internal energy distribution ($P(\epsilon)$ versus internal energy, ϵ) deposited in the collision event. Metal carbonyls are often used due to their simple fragmentation pathway by consecutive losses of CO and well-known critical energies. **Figure 8a** depicts the SID product ion spectrum resulting from 30 eV collisions of $W(CO)_6^{+}$ with an 8 μm thick liquid perfluoropolyether (PFPE) surface, $F[CF(CF_3)CF_2O]_{27(\text{avg})}CF_2CF_3$. The internal energy distribution is then calculated from the mass spectrum in **Figure 8a** using the thermometer molecule method and the result is shown in **Figure 8b**. The distribution is approximately Gaussian in shape with a full width at half maximum (FWHM) of 4.4 eV and an average internal energy of 5.5 eV. The $T \rightarrow V$ conversion efficiency is calculated to be 18%. Although the values calculated in **Figure 8b** are for one particular ion/surface system, it is a general characteristic of SID to produce internal energy distributions which are approximately Gaussian in shape with FWHMs of approximately 4 eV.

Another method used to determine SID internal energy distributions is the deconvolution method. This method relies on the fact that the mass spectrum, breakdown curve (normalized fragment ion intensities as a function of internal energy), or internal energy distribution can be calculated if

Figure 5 Overview of a tandem time-of-flight SID instrument. Reproduced with permission from Riederer Jr, DE, PhD, Department of Chemistry, University of Missouri, Columbia.

two of the three are known. For example, the mass spectrum can be calculated by convoluting the breakdown curve with the internal energy distribution. Since the benzene molecular ion has been well studied and breakdown curves have been measured, the internal energy distribution can be determined by deconvoluting the breakdown curve and the recorded SID mass spectrum of the benzene molecular ion. The deconvolution method has reported slightly higher $T \rightarrow V$ conversion efficiencies than the thermometer molecule method for similar surfaces. Small variations in the

Table 3 Characteristics of the SID process.

1. Internal energy (V) deposition is variable depending on the collision energy (T)
2. Internal energy deposition can be made large; more than 10 eV is readily accessible
3. Internal energy distribution is narrow, typically 4 eV FWHM, and is approximately Gaussian in shape
4. The efficiency of converting translational energy to internal energy is dependent on the nature of the surface and is approximately 20–30% for fluorocarbon surfaces and 10–20% for hydrocarbon surfaces
5. The SID efficiency varies over a wide range 1–75% but is typically more than 10% for most polyatomic ion/organic covered surface pairs
6. Fragment ions are similar to those noted in CID experiments
7. SID is proving to be applicable to large biomolecules

$T \rightarrow V$ conversion efficiency for a given surface have been noted with changes in the chemical composition of the projectile ion (see Table 4).

SID internal energy distributions are very different from those observed in CID. CID internal energy distributions are typically broad in nature and with uncharacteristic shapes. The narrow internal energy distribution found in SID gives a finer control over the energy that is deposited into an ion and thus more control over the extent of fragmentation than CID.

As a result of the high $T \rightarrow V$ conversion efficiencies in SID, large amounts of internal energy can be readily deposited into the projectile ion. For example, experiments using the benzene molecular ion have shown the ability of SID to impart more than 20 eV of internal energy. This large internal excitation and the high $T \rightarrow V$ conversion efficiency are due to the fact that in SID, the projectile ion cannot ‘miss’ its target, that is to say, the ion will always experience ‘head-on’ or small impact parameter collisions, as opposed to CID where ions are more

Figure 7 Surface-induced dissociation ion spectra of the p-methyl phenetole molecular ion (m/z 136) upon collision with an F-SAM surface at (a) 15 eV and (b) 30 eV. likely to undergo larger impact parameter collisions causing less excitation.

Surface Effects

Surface effects in ion/surface collision processes are very prominent and continue to be actively investigated. For example, surfaces covered with hydrocarbon pump oil were found to be more effective in reducing neutralization (or increasing secondary ion yield, that is, the ratio of the total secondary ion current to the primary ion current measured at the surface) than clean metal surfaces. In addition, it was also found that the organic nature of the surface affected the energetics of the ion/surface collision, especially the $T \rightarrow V$ conversion efficiency.

Prior to using organic covered surfaces, SID was performed on clean metal surfaces. The SID efficiency (ratio of the sum of total fragment ion current to the projectile ion current measured at the surface) of these ion/surface systems was often very poor, $<1\%$. For example, collisions of the ferrocene molecular ion with a clean Si(100) surface at 10 eV result in an SID efficiency of 10^{-2} . This can be rationalized by examining the thermochemistry of an electron transfer reaction for the

Figure 8 (a) Surface-induced dissociation mass spectrum produced from 30 eV collisions of $W(CO)_6^+$ (m/z 352) with an 8 μ m thick liquid perfluoropolyether surface. (b) Calculated internal energy distribution for the spectrum in (a) using the thermometer molecule method. **Figure 8a** reproduced with permission from Pradeep T, Miller SA, and Cooks RG (1993) Surface-induced dissociation from a liquid surface. *Journal of American Society for Mass Spectrometry* 4: 769–773.

projectile ion and the surface. For example, a typical ionization energy for an organic compound is 10 eV and that of a clean metal surface is on the order of 3 or 4 eV (known as the work function of the surface). When the ion approaches a clean metal surface, the enthalpy of the electron transfer reaction (from the surface to the projectile ion) is very exothermic, 6–7 eV, and the neutralization of the projectile ion will be very efficient. However, when an organic layer covers the metal substrate, it changes the thermochemistry of the surface from a work function of a few eV to one that is of the order of the neutralization energy of the projectile ion. This change in thermochemistry reduces the exothermicity and extent of neutralization.

Self-assembled monolayer surfaces (SAMs) of n-alkane thiols on gold have become a surface of choice for studying the SID process. These surfaces offer an array of variability in the chemical functionality of the surface, they are stable in vacuum and air, can be well ordered, characterizable, and are relatively simple to fabricate. The most common of the SAM surfaces used in SID studies are the hydrocarbon SAM (H-SAM) and fluorocarbon SAM (F-SAM) surfaces shown in **Figure 2**. Continuing the

thermochemical argument for the electron transfer process above, it would be expected that a fluorocarbon surface would yield higher SID efficiencies due to the larger ionization energy for fluorocarbon molecules, ~ 13 eV, making the electron transfer reaction endothermic for typical organic projectile ions. Note that although the reaction is endothermic, the translational energy of the projectile ion can be used to drive endothermic reactions. Studies have shown that fluorocarbon surfaces have higher total secondary ion yields than hydrocarbon surfaces, with some reports showing the F-SAM surface to have efficiencies of 55–75% as contrasted with 1–35% for H-SAM surfaces. The variation in secondary ion yields for a given SAM surface correlates with the neutralization energy of the projectile ion, that is, the overall thermochemistry of the electron transfer reaction.

The nature of the surface is an influential factor in the $T \rightarrow V$ conversion efficiency for a particular ion/surface pair. **Table 4** lists several thermometer molecules that have been used to determine the $T \rightarrow V$ conversion efficiency for several hydrocarbon and fluorocarbon surfaces. Fluorocarbon surfaces are more efficient at converting

translational energy to internal energy than hydrocarbon surfaces due to a more rigid structure in the F-SAM surface and more massive end-groups. **Figure 9** illustrates the greater effectiveness of the F-SAM surface at dissociating the pyrazine molecular ion than a perdeuterated SAM (D-SAM) surface at the same ion kinetic energy of 25 eV. The F-SAM surface also exhibits a greater signal-to-noise ratio and SID efficiency as a result of reduced neutralization. Note that the pyrazine molecular ion is reactive with the D-SAM surface producing the ion/surface reaction product, $[M + CD_3]^+$, and the ion/surface reaction fragment $[M + D-HCN]^+$. It is interesting to note that the $T \rightarrow V$ conversion efficiency of the liquid PFPE film and an F-SAM surface are almost identical (similar chemical composition) but their physical state of matter is different. There is very little difference in SID and ion/surface reactions between the liquid PFPE and the F-SAM surface for a large variety of projectile ions, supporting the hypothesis that the ion only interacts with the outer layer of the surface.

Applications

Surface-induced dissociation produces structurally diagnostic ions similar to those found in the analogous gas phase CID experiment. For example, **Figure 10a** shows the SID mass spectrum of the pyrene molecular ion at a collision energy of 100 eV with an F-SAM surface. The spectrum displays significant fragmentation by diagnostic C_2 losses. **Figure 10b** displays the CID of pyrene at 100 eV under single collision conditions with Ar and only produces two minor fragment ions. Note that this comparison of SID to CID is made based on specific experimental conditions, namely single collision events for CID. CID is often performed under multiple collision conditions which imparts a larger average internal energy deposition yielding more diagnostic fragment ions. One must be careful when comparing SID and CID since the experimental conditions can greatly bias the observed results. Nonetheless, both ion activation methods provide useful information about ion structure.

Fragment ions produced by SID have been used to distinguish gaseous isomeric ions and to elucidate the structure of biomolecules. The unique characteristics of SID, narrow internal energy distribution and variable control of internal energy, make it a powerful tool for studying isomeric ions. Before low energy ion/surface collisions were used as a means of ion activation, isomeric ion distinction was performed by mass spectrometric techniques such as CID, charge exchange, and kinetic energy release measurements, all of which used high energy collisions. Isomers of $C_5H_6^+$, $C_6H_6^+$, $C_6H_6^{2+}$, $C_2H_3S^+$, $C_2H_4O^+$, and $C_3H_4^+$ have been distinguished by low energy SID. It is worth noting that ion/surface reaction products can serve as a complementary tool when studying isomers in the gas

phase due to the often selective nature of ion/surface reactions.

Activation and dissociation of large biomolecule ions is currently the focus of many investigators interested in analytical applications of SID. As noted in the introduction, the need to activate and dissociate increasingly larger molecules is a constant challenge in tandem mass spectrometry. SID offers the advantage of large $T \rightarrow V$ conversion efficiencies and narrow internal energy distributions. While neutralization in SID can pose a problem, improvements are made by choosing a surface which minimizes the extent of neutralization. Thus, fluorocarbon surfaces are often used in

SID biomolecule applications. SID mass spectra of peptides yield results consistent with low energy CID, that is, the formation of peptide backbone fragments such as a -, b -, and y -type ions. In addition to backbone cleavages, some peptides exhibit side chain specific cleavage ions, d - and w -type, in low energy SID experiments which are normally characteristic of high collision energy (keV) CID data. **Figure 11** illustrates the diagnostic fragments resulting from collisions of the doubly protonated melittin ion with an F-SAM surface at 110 eV. The spectrum consists of mainly backbone cleavage fragments (a -, b -, and y -type) with nearly a complete y -type series from y_2 to y_{25} . A complete primary

sequence of the melittin ion, with the exception of two residues, can be determined from this single SID mass spectrum. These experiments are also lending insight to the energetics and fragmentation mechanisms of peptides due to the controllable nature of the internal energy deposition characteristic of the SID method.

Surface-Induced Dissociation Mechanisms

In most cases, polyatomic fragment ions noted in SID are similar to those found in CID and can be explained by unimolecular fragmentation pathways. This general observation has led to the prediction of a two-step SID mechanism involving the collision which causes internal

excitation followed by a delayed fragmentation some distance and time away from the collision event. This concept for the mechanism of SID of polyatomic *organic* ions is fairly well accepted, although one study has shown evidence for dissociation at the surface interface in a prompt or 'shattering' mechanism for a specific ion/surface pair.

SID mechanisms are typically interrogated by monitoring the kinetic energy or velocity of the scattered product ions. If delayed unimolecular fragmentation is occurring, then the velocity of the scattered fragment ions will be the same as the scattered projectile ion. If a prompt or shattering mechanism is occurring then the scattered product ions will leave the surface with

Figure 11 Surface-induced dissociation spectrum of doubly protonated melittin obtained at a 110 eV collision with a fluorinated SAM surface. different velocities or rather the same kinetic energy. It is not clear if the prompt dissociation mechanism is only specific for certain ion/surface pairs or if both mechanisms commonly occur but to varied extents.

Other Ion/Surface Processes

The examples discussed thus far have been relatively 'clean' examples of SID without the added complexity of peaks resulting from chemical sputtering and ion/surface reactions. There is a growing literature based on observations of chemical sputtering, ion/surface reactions, and ion/surface reactions which lead to selective surface modification in low energy ion/surface collisions. In order to obtain a better understanding of SID, it is important to have an understanding of all of the ion/surface collision processes shown in Table 1.

Ion/Surface Reactions

The organic covered surface can be thought of as a chemical reagent in a reaction that uses the projectile ion as the second chemical reagent. Figure 12 shows the SID mass spectrum for collisions of $(\text{CH}_3)_2\text{SiNCS}^+$ with an F-SAM surface at 50 eV. Peak assignments can be found in Table 5. This spectrum displays a wealth of peaks originating from various ion/surface collision processes including SID, ion/surface reaction, and chemical sputtering. The number and abundance of ion/surface reaction products (especially Si containing product ions) for this ion/surface pair may appear to be remarkable for

Figure 12 50 eV ion/surface collision spectrum of $(\text{CH}_3)_2\text{SiNCS}^+$ on an F-SAM surface. Note that the ion abundance scale has been expanded. For reference, the $\text{M}^+/\text{SiNCS}^+$ ratio is 0.05 and the $\text{M}^+/\text{SiCH}_3^+$ ratio is 0.04. Peak assignments are noted in Table 5. Reproduced with permission from Miller SA, Luo H, Jiang X, Rohrs HW, and Cooks RG (1997) Ion/surface reactions, surface-induced dissociation, and surface modification resulting from hyperthermal collisions of OCNCO^+ , OCNCS^+ , $(\text{CH}_3)_2\text{SiNCO}^+$, and $(\text{CH}_3)_2\text{SiNCS}^+$ with a fluorinated self-assembled monolayer. *International Journal of Mass Spectrometry and Ion Processes* 160: 83–105.

what would intuitively be thought of as a relatively inert fluorocarbon surface. Indeed, it has been found that the F-SAM surface is very reactive towards organometallic, metallic, and a few organic ions.

Figure 13 Product ion spectrum resulting from collisions of the d_6 -benzene molecular ion (*m/z* 84) with an H-SAM surface at 30 eV. The inset represents the associative ion/surface reaction mechanism for the unlabelled benzene molecular ion.

Two distinct ion/surface reaction mechanisms have been elucidated. One ion/surface reaction mechanism occurs by direct abstraction or oxidative addition of an atom or group of atoms from the surface by the projectile ion. This type of mechanism is most often observed for metal-containing ions and fluorocarbon surfaces. For example, collisions of W^+ with an F-SAM surface result

in ion/surface reaction products of the form, WF_n^+ ($n = 1-5$). These reaction products have been shown to occur via the direct abstraction process. The second mechanism occurs by a two-step process of (i) an electron transfer from the surface to the projectile ion and (ii) an associative ion/molecule reaction between the neutralized projectile and a chemically sputtered ion from the

surface. This mechanism is typically observed for hydrocarbon projectile ions and hydrocarbon surfaces. An example of ion/surface reaction which occurs via an associative ion/molecule reaction is shown in **Figure 13**. The neutralized d_6 -benzene, C_6D_6 , reacts with a sputtered proton from the H-SAM surface to form the $[M + H]^+$ product ion. This example also illustrates the advantage of using an isotopically labelled projectile ion. Peak assignments for SID and ion/surface reaction products are less ambiguous than if the $C_6H_6^{*+}$ molecular ion was used as the projectile. It is worth noting that both ion/surface reaction mechanisms have been indirectly supported by the corresponding gas phase ion/molecule experiments.

Chemical Sputtering

Chemical sputtering has been shown to be a very sensitive (submonolayer) surface analysis technique when using appropriate sputtering reagents in low energy ion/surface

collisions. The chemical sputtering peaks originating from the F-SAM surface in **Figure 12** are of low abundance but can be significantly enhanced by using the xenon radical cation which is an efficient charge transfer reagent for fluorocarbon surfaces. For example, **Figure 14** depicts the chemical sputtering spectrum of a fresh F-SAM surface and the liquid PFPE surface. Abundant chemical sputtering peaks representative of the chemical composition of each surface are labelled in the figure. This experiment is also sensitive towards hydrocarbon impurities in the F-SAM surface at m/z 27 ($C_2H_3^+$), m/z 29 ($C_2H_5^+$), m/z 39 ($C_3H_3^+$), m/z 41 ($C_3H_5^+$), and m/z 43 ($C_3H_7^+$). As noted earlier, the F-SAM and liquid PFPE surface produce very similar SID mass spectra. However, chemical sputtering experiments can differentiate the two, due to the characteristic oxygenated fluorocarbon peak at m/z 47, CFO^+ , in the liquid PFPE spectrum. These experiments also suggest that the liquid/vacuum interface microscopic structure is similar to that of the F-SAM surface and the projectile ion only interacts with the outer portion of the surface at these low energies. Note that chemical sputtering is a low energy (reactive) collision which differs from the more common secondary ion mass spectrometry technique that uses keV ion beam (momentum transfer) collisions to analyse surface composition.

Surface Modification

Selective chemical modification of surfaces is also a consequence of low energy ion/surface collisions. For example, one of the many ion/surface reaction products seen in **Figure 12** is of particular interest, $CH_3FSiNCS^+$ (see also **Table 5**). This reaction product may be formed by the following group transfer reaction,

where $F-CF_2-(\text{surface})$ represents the outer CF_3 head group on an F-SAM surface. This reaction would yield a chemically modified surface which would be difficult to fabricate using common surface preparation methods. Xenon chemical sputtering has shown that the $(CH_3)_2SiNCS^+$ projectile ion modifies the F-SAM surface by incorporating NCS, methyl, and silyl groups into the fluorocarbon chain. Other examples of chemical surface modification involving group transfer reactions or trans-halogenation in low energy ion/surface collisions include the interaction of $OCNCS^+$, $SiCl_4^+$, $CH_2Br_2^+$, and CH_2Br^+ with F-SAM surfaces.

Soft Landing

Finally, soft landing of polyatomic ions into self-assembled monolayers can be achieved using appropriate projectile ions with low ion kinetic energies. The projectile ion used in **Figure 12**, $(CH_3)_2SiNCS^+$, can be soft

Figure 14 90 eV Xe^{++} chemical sputtering spectra for (a) and F-SAM surface and (b) an 8 μm thick liquid perfluoropolyether surface. landed in an F-SAM surface by lowering the ion kinetic energy below 10 eV. The soft-landed ion can be subsequently liberated into the gas phase by $\text{Xe}^{\bullet+}$ chemical sputtering. By using chemical sputtering experiments and temperature programmed desorption, the soft-landed species has been shown to survive as an ion in the F-SAM matrix for several days in vacuum and a few days in ambient air. This approach may have exciting implications for both fundamental and applied studies.

Surface Induced Dissociation and Soft Landing Techniques in Mass Spectrometry

Jean H Futrell and Julia Laskin, Fundamental and Computational Sciences Directorate, Pacific Northwest National Laboratory, Richland, WA, USA

Published by Elsevier Ltd.

Introduction

The development of soft ionization techniques, particularly electrospray ionization (ESI) and matrix-assisted laser desorption ionization (MALDI), resulted in an explosive growth of studies that utilize mass spectrometry for identification and structural characterization of large molecules. The most common strategy in these studies involves tandem mass spectrometry (MS/MS), which relies on structurally specific fragmentation of mass-selected ions in the gas phase. Typical MS/MS experiments involve mass selection of the ion of interest in the first MS stage and excitation of the ion followed by its dissociation and mass analysis of the resulting fragment ions in the second MS stage. For small polyatomic ions, the ionization process typically imparts sufficient internal excitation to generate structurally specific fragment ions. However, both ESI and MALDI mainly produce molecular ions with very little, if any, fragmentation. It follows that the ion activation step is of crucial importance for MS/MS studies of large molecules.

It is well known that polyatomic ions require excess internal energy above their dissociation threshold to fragment on the timescale of a mass spectrometer. This excess internal energy is called the kinetic shift (KS), which is modest for small molecular ions but increases dramatically with increasing size of the ion. The practical consequence of this effect is a dramatic decrease in dissociation rates for large ions. Consequently, efficient dissociation of large ions in a mass spectrometer requires deposition of large amounts of internal energy. This can be achieved using multiple gas-phase collisions, multiphoton excitation, or collision with a suitably prepared surface. In multiple-collision activation or infrared multiphoton excitation, the internal energy of the ion undergoes small increments and dissociation occurs when sufficient internal excitation is absorbed by the ion. An alternative approach introduced by Cooks and his collaborators relies on very fast, single-step excitation of the ion in collision with a surface, surface-induced dissociation (SID). Physical and chemical properties of the surface play an important role in determining the outcome of the collision. In the range of ion kinetic energies utilized in SID studies (0–200 eV), the major competing process with ion scattering is the neutralization or capture of the precursor ion on the surface. More than 99%

of projectile ions are neutralized in collisions with metal surfaces. However, organic surfaces (self-assembled monolayers (SAMs) of alkylthiols on gold, Langmuir–Blodgett (L–B) films on metal substrates, highly oriented pyrolytic graphite (HOPG), or thin films of insulating materials (e.g., diamond and LiF) on conducting surfaces) significantly decrease neutralization and are excellent targets for SID. Using these specialized surfaces, relatively high efficiency of conversion of translational energy into internal excitation is easily achieved. A major application of SID is the structurally specific fragmentation of peptides and proteins, and most of the examples cited in this article involve peptides.

Soft landing (SL) of ions on surfaces – the deposition of intact ions onto solid or liquid surfaces – efficiently competes with scattering and SID at low-to-moderate collision energy. Consequently, preparatory mass spectrometry based on SL of mass-selected ions is a viable approach for high-purity, position-specific surface modification. Controlled deposition of complex ions onto surfaces is also of interest as a probe for obtaining molecular-level understanding of interactions of large molecules and ions with selected substrates. These processes will be described briefly in the last section.

First instrumental implementation of SID is discussed in several tandem mass spectrometers, including Fourier transform ion cyclotron resonance mass spectrometry (FT-ICR MS). External mass selection and accumulation of ions is an important prerequisite for SID in FT-ICR. These ion preparation techniques are now well developed and incorporated into most commercial FT-ICR MS instruments. The distinctive features observed for SID of peptide ions impacting on a carefully chosen, representative SAM on gold surface are summarized in this article. The importance of the surface is next illustrated comparing SID on soft (e.g., SAM) and hard (e.g., diamond) surfaces. The article is concluded with a discussion of nonreactive ion capture and reactive collisions.

Instrumentation for SID

Extremely fast ion activation distinguishes SID from other activation techniques for large molecules. This property and the relative ease of controlling ion activation make it a preferred excitation method for characterizing molecules that are difficult to fragment and identify using traditional

slow activation methods. SID has been implemented on a variety of instruments including tandem quadrupole (QQ) mass spectrometer linear and reflectron time-of-flight (TOF) mass spectrometers (**Figure 1**), sector instruments, and an FT-ICR mass spectrometer (**Figure 2**). Other modifications include the interesting tandem application by Russell and coworkers, who coupled SID with ion mobility for improved identification of peptides in proteomics. For FT-ICR, a major advantage of SID is that activation occurs under high vacuum conditions, dramatically shortening acquisition times for MS/MS experiments. Since activation is essentially instantaneous in SID, the time delay between excitation and mass analysis becomes a conveniently controlled experimental variable for investigating ion dissociation kinetics.

Figure 2 is a schematic description of the current (2008) version of a FT-ICR-SID instrument. Features include a high-transmission electrospray interface fitted with an ion funnel for maximizing ion transmission and a collisional quadrupole that relaxes ion velocities and transmits ions into a low-pressure commercial mass-resolving quadrupole. Mass-resolved ions are accumulated and thermalized in the third quadrupole. The kinetic energy of ions impacting the surface is controlled by a DC offset applied to the ICR cell within the high magnetic field, where ion beam trajectories

are unperturbed by deceleration optics. The SID surface is introduced to the rear trapping plate of the ICR cell using a custom probe and vacuum-lock system. Scattered ions are captured by gated trapping in a cylindrical quadratic ICR cell that can be operated with much higher trapping voltages than conventional ICR. A recent addition shown in the figure is an 8 keV Cs ion gun secondary ion mass spectrometry (SIMS) probe to interrogate surface composition during and after ion bombardment.

Fundamental Characteristics of SID

Before describing general characteristics of SID, it should be noted that several properties of both the ion and the surface define the outcome of ion–surface collisions. For the experiments summarized in this article, the ensemble of impacting ions has a quasi-thermal distribution of internal energies (achieved by collisional relaxation in the storage quadrupole of **Figure 2**) when surface impact occurs. The optimized surface is a 12-carbon unit SAM on gold, a chain length long enough to reduce neutralization by nearly two orders of magnitude and short enough to prevent surface charging that would deflect the impacting ion beam or perturb its kinetic energy.

Influence of Ion Kinetic Energy

The efficiency of translational-to-vibrational ($T \rightarrow V$) energy transfer is one of the key factors determining the fate of scattered ions. **Figure 3** compares the most probable internal energies deposited in protonated dialanine (E_{mp})

Figure 3 The most probable internal energy deposited in protonated dialanine by multiple collisions (red) and ion-surface interaction (blue). E_{mp} is plotted as a function of the maximum center-of-mass (CM) collision energy for MCA-CID and the 'effective' CM energy for SID. Reproduced from Laskin J, Denisov E, and Futrell JH (2001). Comparative study of collision-induced and surface-induced dissociation. 2. Fragmentation of small alanine-containing peptides in FT-ICR MS. *Journal of Physical Chemistry B* 105: 1895–1900, with permission from the American Chemical Society, copyright 2001.

by SID and multiple-collision CID (MCA-CID) as a function of the center-of-mass collision energy. E_{mp} for SID rises almost linearly with collision energy, whereas for MCA-CID the curve falls below linear dependence as energy increases. This is a result of collisional deactivation of hot ions by gas-phase collisions – an energy loss channel that does not exist for SID. At higher energies, the relative advantage of SID is even more pronounced.

Figure 4 presents for a model peptide, des-Arg⁹-bradykinin, an overview of kinetics features for impacting the singly protonated molecular ion of a representative peptide on a fluorinated SAM as a function of ion impact energy. This figure, with its inset representative mass spectra, summarizes two principal SID reaction mechanisms. In the energy range from 12 to 20 eV, the fragment ions b_2 and y_6 and a water loss peak – the lowest energy dissociation pathways for this ion – are the only product ions. As collision energy is increased, the number of product ions increases dramatically. Most of the high-energy fragments are formed by very fast dissociation pathways. This prompt dissociation has been described as shattering of ions on surfaces; it is the dominant mechanism when the internal energy of the ion exceeds 10 eV.

The shattering transition illustrated in **Figure 4** for this peptide has been previously reported for cluster ions and small molecules. It has also been predicted in trajectory simulations for collisions of protonated glycine with diamond. Shattering of peptide ions opens up a variety of dissociation pathways that cannot be accessed using slow ion activation and results in formation of mainly backbone fragments including a large number of

Figure 4 Number of peaks in the SID spectrum of protonated des-Arg⁹-bradykinin impacted on a fluorinated SAM surface as a function of ion collision energy. Insets illustrate the mass spectra at the energies indicated by the arrows. Reproduced from Laskin J, Bailey TH, and Futrell JH (2003) Shattering of peptide ions on self-assembled monolayer surfaces. *Journal of the American Chemical Society* 125: 1625–1632, with permission from the American Chemical Society, copyright 2003.

internal fragments and immonium ions. These ions are often much more informative about the structure of the parent peptide than primary fragments produced by low-energy dissociation pathways. It is also noted that the shattering mechanism is readily accessed by changing the voltage applied to the surface. This enables rapid switching between predominantly slow (rearrangement, statistical) and predominantly fast dissociations.

Shattering of complex ions on surfaces is a direct result of very fast excitation of vibrational degrees of freedom in repulsive ion–surface collisions. Molecular dynamics simulations have shown that significant distortion of the precursor ion in the collision event generates high-amplitude excitation of vibrational modes. This sharply contrasts with multiple-collision activation in which single collisions only weakly perturb the original structure of the ion.

Fast Excitation

Another important advantage of fast ion activation is illustrated in **Figure 5** by a hypothetical potential energy surface for the formation of two fragments from the precursor ion. The left panel represents ion activation by a single collision with a surface, and the right panel depicts slow activation by, for example, multiple gas-phase collisions. For the latter example, a collision that imparts energy just above the lowest fragmentation threshold (internal energy E_1) either is activated by another collision or decomposes to fragment F_1 . If the dissociation rate constant exceeds the collision frequency, the upper channel is not populated. It follows that SID populates higher energy channels more efficiently than slow activation methods. The effect is more pronounced when

Figure 5 Schematic presentation of the potential energy surface for the formation of F_1 and F_2 from the precursor ion activated by ion–surface impact (left panel) and multiple collisions (right panel). there is a significant difference in threshold energies for the two competing pathways.

This concept was very effectively exploited by Wysocki and coworkers in the example illustrated in **Figure 6**. This figure compares gas-phase multiple-collision activation and SID spectra obtained for the +11 charge state of the cytochrome c dimer. Partial unfolding of the protein before fragmentation in CID experiments favors asymmetric charge partitioning, while rapid excitation above the dissociation threshold by SID favors symmetric fragmentation of the protein dimer.

Influence of SID Target Composition

As noted earlier in the section Fundamental Characteristics of SID, optimum properties of an SID target include a relatively low neutralization efficiency and sufficient conductivity to prevent surface charging effects. Current SID targets with these characteristics include self-assembled monolayers of n -alkanethiols (HSAM) and their fluorinated analogs (FSAM) on gold or silver, L–B films, or highly oriented pyrolytic graphite or thin films of insulating materials (such as metal halides or diamond) on metal substrates. FSAM, HSAM, diamond, and LiF surfaces provide comparable spectral intensities of scattered ions; total scattered ion intensity at moderate collision energies is of the order of 30%.

Another important consideration for the proper choice of SID target is the efficiency of $T \rightarrow V$ energy transfer. It is well known that the efficiency of energy transfer is higher for fully or partially fluorinated films (18–28% for FSAMs) than for CH_3 -terminated films (10–17% for HSAMs) of alkylthiols. Classical trajectory simulations have also demonstrated that surface stiffness is a principal factor governing energy transfer efficiency. Such simulations have suggested that diamond should be two to three times more efficient than HSAM in collisional excitation of impacting ions from small peptides. This prediction is strongly supported by experimental studies.

The width of the energy deposition function (EDF) is also strongly affected by the properties of the SID target, as shown quantitatively for these surfaces in **Figure 7**. Here the shape of the EDF for 50 eV collisions of singly protonated des-Arg¹-bradykinin with an FSAM surface is compared to EDFs for diamond, LiF, and HSAM surfaces that deposit the same average energy. A thermal distribution at 920 K is shown for comparison. The width of the EDF increases in the following order: HSAM < FSAM < LiF < diamond. Relatively narrow EDFs are obtained for collisions with the two SAM surfaces, and both distributions are well approximated by a thermal distribution of energies. Collisions with stiff, crystalline surfaces produce a wider distribution of internal energies in SID.

These findings have several important practical implications for optimum selection of SID targets.

Figure 6 Comparison of charge-state distributions obtained for the +11 charge state of cytochrome c dimer activated by slow (multiple-collision CID) and fast (SID) activation. A much more symmetric distribution of charge states is obtained for SID. Figure 7 Comparison of EDFs resulting in the same most probable internal energy deposition relative to 50 eV collisions of singly protonated des-Arg¹-bradykinin with FSAM surface (red). Collision energies are 53 eV for diamond (blue), 86 eV for LiF (magenta), and 102 eV for HSAM (green). 920 K thermal distribution (black) shown for reference. Reproduced from Laskin J and Futrell JH (2003). Energy transfer in collisions of peptide ions with surfaces. *Journal of Chemical Physics* 119: 3413–3420, with permission from the American Institute of Physics, copyright 2003.

Specifically, investigation of the details of fragmentation of complex ions should utilize the SAM surfaces that are well represented by narrow, Boltzman-like internal energy distributions. Conversely, for accessing both low-energy and high-energy excitation mechanisms, diamond is ideal. This is illustrated in **Figure 8**, which shows comparison of SID spectra obtained for diamond and HSAM surfaces at collision energies chosen to deposit the same average internal energy. HSAM SID readily resolves low-energy and high-energy mechanisms, whereas diamond SID populates both energy ranges.

These points are further illustrated in **Figure 9**, comparing diamond SID with multiple-collision activation for sequencing of singly protonated peptide ions generated by MALDI. Fragmentation spectra for a singly protonated 14-residue peptide (DRVYIHPFHLVYS) are compared for CID and SID for this example. Although CID spectra contain only fragment ions corresponding to multiple water losses from the precursor ion and one backbone y_{13} fragment ion, SID spectra contain a large number of sequence-specific fragment ions. Clearly, SID generates significantly better sequence coverage for complex ions than CID or other slow ion activation techniques.

Figure 8 SID spectra of des-Arg¹-bradykinin obtained using diamond (left panel) and HSAM (right panel) surfaces. Collision energies were chosen to match the most probable energy deposition for both surfaces. Both at high and low collision energy, better sequence coverage is obtained using the diamond surface. Fundamental Applications of SID

FT-ICR-SID is very useful for accurately determining the energetics and dynamics of dissociation of complex ions. Specific advantages provided by SID include very fast ion activation, which eliminates possible discrimination against higher-energy dissociation pathways, and highly sensitive detection of small changes in dissociation parameters. For example, the shift in collision energy required to dissociate isomeric model peptides des-Arg¹- and des-Arg⁹-bradykinin is 4 eV, whereas the thermochemical threshold difference is only 0.08 eV. Two effects account for this ‘amplification’ of subtle variations in threshold energies. First, there is a substantial KS for dissociation of ions of this size even on a long timescale of the FT-ICR experiment. For this example, the difference in KS for dissociation of these peptides at 1 s reaction delay is 0.8 eV, a factor of 10 amplification of the difference in thermochemical thresholds. Secondly, the T→V transfer efficiency is approximately 20%, requiring a fivefold shift in ion kinetic energy to increase

the internal energy by an incremental amount. Combining these two factors leads to a 50-fold amplification of the kinetic energy difference for slowly fragmenting peptides, enabling precise measurement of very small differences in thermochemical thresholds.

In addition to providing important information on the appearance energies of different fragment ions, FT-ICR-SID enables direct observation of dissociation kinetics of ion decomposition. Varying the delay between ion-surface collision and the analysis of resulting fragments enables quantitative kinetic studies. Time- and energy-resolved FT-ICR-SID studies of a number of peptide ions have demonstrated a great potential for detailed elucidation of fragmentation energetics and mechanisms.

Soft Landing of Ions on SAM Surfaces

There are a number of reasons why SL of hyperthermal ions onto surfaces is an attractive area for both fundamental studies and applications. Controlled deposition of

complex ions of exquisitely defined composition onto a well-defined location on a surface is a new approach for investigating molecular-level interactions of large molecules and ions with a variety of substrates and dissecting details of transport of small ions through liquid films. SL is also an attractive approach for controlled, highly specific modification of substrates. Potential applications include purification of compounds from complex mixtures, preparation of novel substrates for enrichment and analysis of phosphopeptides in complex mixtures, deposition of mass-selected cluster ions on substrates, preparation of protein or peptide arrays, and controlled preparation of new types of nanoscale materials, such as nanocatalysts, nanomagnetics, nanoelectronics, and biological microarrays. Several examples of recent applications of SL are shown in **Figure 10**. These include trapping of polyatomic ions on FSAM surfaces (**Figure 10a**), covalent modification and patterning on reactive hydroxyl-terminated SAMs (**Figure 10b**), preparation of novel carbon films using SL of reactive C_{58}^+ ions (**Figure 10c**), preparation of grapheme films (**Figure 10d**), and preparation of protein microarrays (**Figure 10e**).

First reported by Cooks and coworkers in 1997, charge retention by ions soft landed onto SAM surfaces is a particularly interesting outcome of ion-surface collisions. This phenomenon has been investigated using the **Figure 2** apparatus that enables SIMS interrogation of surface

composition during and following SL. As an example, the time-dependant SIMS interrogation of SL of doubly protonated gramicidin S (GS) on an FSAM surface demonstrated rapid increase in doubly protonated, singly protonated, and neutral GS during ion deposition. The doubly protonated GS primary ion SIMS signal declines exponentially once the ion beam is turned off. The singly protonated and neutral SIMS spectra exhibit quite different, mixed decay processes. The singly protonated species signal increases for 2–3 h after ion deposition is turned off, demonstrating that proton transfer from the doubly charged ion to the substrate is an important reaction mechanism. The simplest kinetic model that rationalizes these observations involves charge reduction by the loss of a proton, thermal desorption of ions and neutral GS molecules from the surface, reionization of neutral and singly protonated molecules, and rapid deprotonation during ion-surface collisions. The decay of the $[GS + 2H]^{2+}$ ion occurs mainly by proton exchange to form $[GS + H]^+$, whereas the singly protonated species mainly decays by thermal desorption. The unique time dependence for $[GS + H]^+$ reflects rapid population of this charge state on the surface by deprotonation of the soft-landed $[GS + 2H]^{2+}$ ion accompanied by much slower desorption. Most of the neutral GS molecules and a small fraction of $[GS + H]^+$ ions are formed in the initial collision step.

Replacing the CF_3 terminal group with a reactive moiety enables the reactive deposition of complex ions,

Figure 11 Cartoon illustration of covalent linkage peptide synthesis linkage by soft landing. Reproduced from Wang P, Hadjar O, and Laskin J (2007) Covalent immobilization of peptides on self-assembled monolayer surfaces using soft-landing of mass-selected ions. *Journal of the American Chemical Society* 129: 8682–8683, with permission from the American Chemical Society, copyright 2007.

specifically exploring attaching certain structure motif peptides to surfaces. Such peptide-modified surfaces are commonly used in biological and medical applications ranging from characterization of molecular recognition events at the amino acid level and identification of biologically active motifs in proteins to the development of novel biosensors and substrates for improved cell adhesion. Existing techniques for linking peptides to SAMs are based on solution-phase synthetic strategies and require relatively large quantities of highly purified material. In contrast, reactive landing of peptide ions on SAM surfaces enables highly specific preparation of the reactant using technical-grade starting materials.

Figure 11 is a recent example illustrating covalent immobilization of a peptide ion onto the self-assembled monolayer terminated with a labile *N*-hydroxysuccinimidyl ester group (NHS-SAM). It is remarkable that reactive landing of doubly protonated ions of a cyclic c(-RGDfK-) peptide on the NHS-SAM for 4 h results in local surface coverage of more than 60% of a monolayer equivalent to the coverage obtained following 2-h solution-phase reaction. The estimated amount of material required for solution-phase surface modification was 50 times larger than for the reactive landing experiment.

SL of mass-selected peptide ions can also be used for preparation of conformation-specific peptide arrays on SAM surfaces. For example, the $[\text{Ac-A}_{15}\text{K} + \text{H}]^+$ model system exists in solution in a predominantly β -sheet conformation but converts to the more stable α -helical conformation in the gas phase. Deposition of the Ac-A₁₅K directly from solution onto SAM surfaces favors the β -sheet structure, whereas SL of $[\text{Ac-A}_{15}\text{K} + \text{H}]^+$ ions from the gas-phase deposits an α -helical peptide layer. Reactive deposition of $[\text{Ac-A}_{15}\text{K} + \text{H}]^+$ on an NHS-SAM results in covalent immobilization of the α -helical conformation. Clearly, surface modification by SL of low-energy ions provides unique opportunities for selective preparation of a variety of new substrates for applications in biology, biomaterials sciences, and catalysis.

As described in the article on the theory of surface plasmon resonance, surface plasmons create a surface-bound evanescent electromagnetic wave which propagates along the surface of an active medium (usually a thin metallic film), with the electric field intensity maximized at this surface and diminishing exponentially on both sides of the interface. As a consequence of this property, the phenomenon has been utilized extensively in studies of surfaces and of thin dielectric films deposited on the active medium. Although numerous other optical techniques have also been applied to such systems (e.g. ellipsometry, interferometry, spectrophotometry, and microscopy), the surface plasmon resonance (SPR) method has some important advantages over all other optical techniques, as follows. The method utilizes a relatively simple optical system, it has a superior sensitivity, and the complete system of measurement is located on the side of the apparatus that is remote from the sample, and thus there is no optical interference from the bulk medium. Furthermore, the surfaces of the sample need no extra

treatment to increase reflectivity, because this is achieved by using total reflectance. Additional benefits include the fact that there are three parameters of the resonance that can readily be measured, thereby yielding much more information about the sample and changes within it than the simple interferometric step height used in other sensitive optical techniques. Finally, the more recently developed new variant of SPR, which involves both plasmon and waveguide modes producing coupled plasmon waveguide resonance (CPWR), expands spectroscopic sensitivities and capabilities even further, allowing the measurement of anisotropies in both the refractive index and extinction coefficient.

Current interest in the properties of surfaces and surface coatings arises partly from increased applications of thin film devices, including the large field of integrated optics, which uses surface guided waves, and partly from developments in biosensors. In addition, many surface phenomena depend on molecular interactions occurring at dielectric interfaces. Surface chemistry applications include charge transfer interactions, acid–base chemistry, chemical bond formation, and van der Waals forces, all of which participate in the processes of adhesion, catalysis, lubrication, corrosion, contamination and packaging. Surface and interfacial phenomena are also of particular importance in all areas of biology, where molecular phenomena occurring at lipid membrane interfaces or during protein–protein interactions are key events in living systems.

This article focuses on the application of the two major properties of the surface plasmon (SP) evanescent wave (i.e. its identity as a surface-bound and surface-unique electromagnetic phenomenon), to the characterization of the properties of surfaces, interfaces, and thin films. It describes the two principal experimental modes, kinetics and spectroscopy, which are currently used in these SPR applications.

Principles of SPR Applied to Thin Films

As described in the article on the theory of surface plasmon resonance, plasmons are transverse magnetic (TM; p -polarized) evanescent waves generated at the expense of light energy under total internal reflection conditions, which propagate along an active medium surface (usually silver or gold) with their field amplitudes

decaying exponentially perpendicular to the metal surface. They obey the well-known dispersion relation, and can only be excited when matching energy and momentum conditions between photons and surface plasmons are fulfilled, as follows:

$$K_{SP} = K_{ph} = (\omega/c)\epsilon_0^{1/2} \sin \alpha_0 \quad [1A]$$

where:

$$K_{SP} = \omega/c(\epsilon_1\epsilon_2/\epsilon_1 + \epsilon_2)^{1/2} \quad [1B]$$

is the longitudinal component of the SP wave vector, K_{ph} is a component of the light wave vector parallel to the active medium surface, ω is the frequency of the surface plasmon excitation wavelength, c is the velocity of light *in vacuo*, ϵ_0 , ϵ_1 , and ϵ_2 are the complex dielectric constants for the incident, surface active, and dielectric (or emerging) media, respectively, and α_0 is the incident coupling angle.

As can be seen, the resonance condition stated in eqn [1A] can be fulfilled by either changing the incident angle, α , at a constant value of photon energy, $h\omega$ (i.e. maintaining a constant value of the light wavelength, $\lambda = \lambda_0$; see **Figures 1a** and **1c**, curve 1), or varying λ at a constant value of the incident angle, $\alpha = \alpha_0$ (see **Figures 1b** and **1d**, curve 1). This means that each photon of energy $h\omega$ allows the excitation of exactly one SP mode at a distinctive value of the incident angle, α , within a specified metallic layer (silver or gold). Furthermore, any alteration in the optical parameters (described by the complex dielectric constant, ϵ , in eqn [1B], which contains the refractive index, n , and extinction coefficient, k) of the metal–emerging medium interface will affect the K_{SP} value and therefore change the resonance characteristics, as indicated by eqn (1A). Thus, deposition of any thin dielectric film (sensing layer) on a metallic surface introduces changes in the optical parameters of the metal–emerging medium interface, thereby causing a shift of the SP wave vector to a larger value:

$$K'_{SP} = K_{SP} + \Delta K_{SP} \quad [2]$$

According to eqn [1A], such a shift of the SP wave vector moves the resonance to either a higher incident angle, α_1 , at a constant value of exciting light wavelength, λ_0 , or a longer exciting light wavelength, λ_1 , at a constant value of the incident angle α_0 , as shown in all parts of **Figure 1** (curves 2).

The spectra presented in **Figure 1** demonstrate that the angular (or wavelength) position and shape of the resonance curve is very sensitive to the optical properties of both the metal film and the emergent dielectric medium adjacent to the metal surface. This property is one of three major attributes of SPR which constitute the foundation for the application of surface plasmons (via their interactions with the medium in which they propagate) as an optical probe of the properties of any material in contact

with an active layer capable of generating this effect. The other two attributes can be stated as follows: (i) The evanescent electromagnetic field generated by the free-electron oscillations is strongly enhanced as compared with the electromagnetic field of the exciting light, and reaches its maximum at the metal–emerging dielectric medium interface. The enhancement of the field at the metal–dielectric interface magnifies the spectral features of the interface, making optical measurements with the SP electromagnetic waves possible. (ii) The evanescent electromagnetic field generated in the film decays exponentially with penetration distance into the emerging medium, i.e. the depth of penetration into the dielectric material in contact with an active metal layer extends only to a fraction of the light wavelength used to generate the plasmons. This makes the phenomenon sensitive *only* to the metal–dielectric interface region, without any interference from the bulk volume of the dielectric material or any medium that is in contact with it.

As a consequence of these characteristics, SPR is ideally suited to probe a few nanometres from the metal surface, a distance well below the wavelength of the light used to generate the plasmons. In essence, the surface plasmon technique can be likened to a multiple-beam interferometer, with one narrow reflected fringe, and is therefore capable of similar sensitivity. In contrast, however, it allows optical measurements to be made of dimensions that are one-thousandth of a wavelength or less, which is well below the sensitivity limits of the other optical techniques (e.g. ellipsometry, spectrophotometry, and various forms of microscopy) used in studies of surfaces and thin films.

Analysis of SPR Spectra

As illustrated above, SPR spectra can be presented either in the form of reflectance (R) as a function of incident angle (α):

$$R = f(\alpha)_{\lambda_0} \quad [2A]$$

or as a function of the excitation light wavelength (λ):

$$R = f(\lambda)_{\alpha_0} \quad [2B]$$

Such spectra incorporate information about the following three parameters, refractive index, n , extinction coefficient, k , and thickness, t , which describe the optical properties of both the metal and the dielectric layers. The influence of these parameters on the angular (or wavelength) *position*, the angular (or wavelength) *width*, and the *depth* of the SPR spectrum is completely contained in the characteristic matrix of the thin film assembly, which allows a determination of their values.

Figure 1 Influence on the theoretical SPR spectra generated with either silver (panels a and c) or gold (panels b and d) films (curves 1 in all panels), and represented by reflectance vs. either incident angle (panels a and b), or excitation light wavelength (panels c and d), of a thin sensing layer deposited on the metallic surface (curves 2 in all panels). The incident and emerging media are glass ($n_g = 1.5151$) and water ($n_w = 1.33$), respectively.

Structural Analysis of Thin Dielectric Films

As demonstrated in **Figures 2** and **3**, the above-mentioned three optical parameters of a thin dielectric film deposited on a metal surface are well separated in their effects on the SPR spectra. Therefore, the experimental

spectra interpreted in the context of the characteristic matrix of the assembly allow a unique evaluation of n , k , and t . The evaluation procedure is based on fitting a theoretical resonance curve to the experimental one. As also indicated in **Figures 2** and **3**, the CPWR method

Figure 2 Changes in the p -polarization component of a theoretical SPR spectrum generated with a CPWR device, comprising a silver layer coated with a 460 nm SiO_2 film, caused by alterations in either the refractive index (a), the thickness (b), or the extinction coefficient (c), of a light-absorbing dielectric sensing film deposited on the silica film. The incident and emerging media are both as described in Figure 1.

provides a means for determining the optical parameters using both TM (p) and transverse electric (TE) (s) polarizations of the excitation light, resulting in two values of the refractive index (n_p and n_s) and two values of the extinction coefficient (k_p and k_s). These parameters can

then be used to calculate the anisotropy of n and k , thereby describing the degree of both molecular order (by the anisotropy in n) and orientation of chromophoric groups attached to the molecules comprising the thin film (by the anisotropy in k). Such information, taken

Figure 3 Changes in the s-polarization component of a theoretical SPR spectrum obtained with the CPWR device described in **Figure 2**, by alterations in either the refractive index (a), the thickness (b), or the extinction coefficient (c), of a light-absorbing dielectric sensing film deposited on the silica. The incident and emerging media are the same as in **Figure 1**.

together with the film thickness (t), provides insights into the microscopic structure of the film. Furthermore, the optical parameters can also be employed to calculate the mass of a deposited thin layer (see next section for details).

It has to be emphasized that all of these characterizations can be obtained using a single device (in this case, CPWR), containing a metal film covered with a dielectric layer, and using a measurement method that involves only a determination of reflected light intensity

under total reflection conditions as a function of either incident angle or light wavelength.

Determination of Thin Film Mass

As noted above, the values of the n , k , and t parameters of a thin film layer deposited on the surface of a metal film contain information about the amount of material in the layer. There are two different ways of calculating the adsorbed mass from the refractive index value. The first approach is based on the assumption that the refractive index increment, dn/dC , is independent of the concentration, C , of the adsorbed substance. If this is so, the surface density, D_s , i.e. the amount of material per unit surface area, can be evaluated by the following expression:

$$D_s = t[(n - n_2)/(dn/dC)] \quad [3]$$

where n and n_2 are refractive indices of the adsorbed thin film and the emerging medium, respectively, and dn/dC is the refractive index increment of the adsorbed substance. Equation [3] can of course only be used if the refractive index increment is known, and depends on the assumption that the value of the increment is constant over the concentration range of the adsorbed material.

The second method of mass calculation is based on the Lorentz–Lorenz relation which can be presented in the most general case, i.e. when the deposited layer contains a mixture of substances, by the following equation:

$$(n^2 - 1)/(n^2 + 2) = A_1 N_1 + A_2 N_2 + \dots \quad [4]$$

where A_i and N_i are the molar refractivity and the number of moles of substance per unit volume, respectively. For a pure substance, a mass density, D , defined as mass per unit volume of adsorbed material, can be directly related to the refractive index by the following equation:

$$D = MN = M/A[(n^2 - 1)/(n^2 + 2)] \quad [5]$$

For an adsorbed layer of thickness t formed from such a pure substance, the above equation can be used to calculate the adsorbed mass (M) in $\mu\text{g per cm}^2$, as follows:

$$M = Dt = 0.1 M/A \{t[(n^2 - 1)/(n^2 + 2)]\} \quad [6]$$

where the thickness is expressed in nanometres. Such a simple mass calculation becomes more complicated when a surface layer is formed from a mixture of substances, as it often is in real measurements. This complexity can, however, still be dealt with, depending upon the specific experimental conditions.

Applications of the SPR Technique

The SPR measurement can be performed, as with other optical measurements, in two modes. Used in a spectroscopic mode, i.e. by measuring and analysing the entire resonance spectrum, SPR provides a tool for the characterization of the microstructural properties of thin films, including thickness, mass distribution (packing density) within the film, and degree of order (orientation) of molecules and of chromophore groups attached to the molecules within the film. In addition, when combined with emission measurements, i.e. emission excited by the surface plasmon electromagnetic field, it can also provide a *molecular orientation distribution*.

When used in a kinetic mode, i.e. by measuring and analysing the changes of reflectance as a function of time at $\alpha = \alpha_0 = \text{const.}$, and $\lambda = \lambda_0 = \text{const.}$:

$$R = f(\text{time})_{\alpha_0, \lambda_0} \quad [7]$$

this experimental approach provides a means for real-time analysis of molecular interactions.

Steady-State and Kinetic SPR Measurements

As a consequence of the above-mentioned characteristics, SPR is ideally suited to studying both structural and mass changes of thin films, including molecular interactions occurring at surfaces and interfaces. These can be examined using either steady-state or time-resolved SPR spectroscopy, and can be applied to a wide range of materials. The time-resolved mode expands the capability of SPR techniques to allow probing of the dynamics of structural and mass alterations of thin films.

Although the phenomenon initially has been utilized extensively by physical scientists in studies of the properties of surfaces and thin films, with a major goal of creating thin film-based opto-electronic devices for optics, spectroscopy, laser optics, solar energy conversion, and space technology, the implementation of this technology to chemical, and especially to biological processes, has proven to be one of the most dynamic and fruitful application areas during recent years. The molecular mechanisms underlying biological and chemical processes are dependent on direct interactions between (bio)molecules. These interactions are often preceded by specific binding between two or more molecules, and for binding to occur the molecules must be able to come close enough to each other to make contact. Such binding may take place between the partners in solution, or with at least one partner attached to a biological surface (e.g. a lipid membrane or a chromosome) or to a physical surface. In situations in which the interactions occur at a surface, there must be a mechanism, such as lateral diffusion in the surface plane, that permits them to come

close enough for interaction. These binding processes will not only result in alterations in the mass and composition of the membrane or other surface, but may also cause structural changes within such entities as well.

The simplest case of a biomolecular (or chemical) interaction is the association of two molecules, X and Y , to form a complex XY . This process is characterized by rate constants for association, k_{ass} , and dissociation, k_{diss} , and an equilibrium (binding or binding affinity) constant, $K_B = k_{\text{ass}}/k_{\text{diss}}$. Steady-state SPR measurements, by determining mass density changes occurring in molecular assemblies accompanying binding interactions, allow an evaluation of the binding constants K_B . Kinetic SPR measurements enable direct observation in real time of such binding events, resulting in determination of association and dissociation rate constants (as discussed in the next section), as well as the dynamics of binding-induced structural changes.

The ability of SPR to probe both kinetic and thermodynamic processes, as well as to provide microstructural information, makes it a very important component of the experimental methodology available to probe molecular interactions occurring at surfaces. Furthermore, it allows some of the limitations of other techniques to be overcome. For example, other methods often require one of the partners to be labelled in some way in order to allow it to be detected. Fluorescent probes, radioactive labels, and attachment of independently detectable molecules (e.g. enzymes) have all been used for this purpose. These suffer from the drawback that they may interfere with the binding of the labelled partner to the unlabelled one, or cause unwanted structural perturbations. SPR observations can be based solely on the dielectric properties of molecules, or their intrinsic light absorption characteristics, and thus require no specific labelling.

Association and Dissociation Rate Constant Measurements

The most straightforward application of SPR technology is the measurement of binding kinetics, i.e. association and dissociation rate constants. This usage is based on the following requirements: First, the binding of one molecule to another, in which one of the molecules is immobilized on the surface of an SPR device, must produce a change in the refractive index, n , of the interface which results in an alteration of the SPR spectrum. This condition is only valid when the SPR exciting light wavelength is outside of the absorption spectral region of both interacting molecules, and when the interaction does not induce any structural changes in the interface. Second, the changes in n are assumed to be proportional to the surface concentration of bound molecules, C , i.e. $dn/dC = \text{constant}$ over the whole concentration range. This

assumption can give rise to some error, especially at high concentrations where the proportionality might not be fulfilled. Third, the changes in n cause *only* a shift of the resonance curve without any alterations in its shape, which is a simplification of the theoretical influence of n on the resonance curve as determined by the characteristic matrix of the thin film assembly. Under these assumptions, changes in the n -value can easily be measured by the shift of the SPR resonance curve. This can be greatly simplified by monitoring the reflectance taken at one specific point of the resonance curve as a function of time, as described by eqn [7]. Such a simple optical measurement allows one to directly probe the molecular interaction by monitoring association and dissociation processes in real time.

Additional Applications of SPR

Additional applications of the SPR phenomenon include using the surface plasmon electromagnetic waves to excite emission of surface-bound chromophores, to enhance Raman spectra (surface-enhanced Raman spectroscopy), and as 'surface-bound light' in optical microscopy.

Sensitivity of Various Types of Surface Plasmon Resonances

The sensitivity, S , of an SPR measurement can be defined as the change in reflectance, measured either at a specified angle, α_1 , or a specified wavelength, λ_1 within the range of the resonance curve, divided by the change in one of the optical parameters, i.e.

$$\text{either } S_{\alpha 1} = [dR_{(\alpha)}/dn \, dk \, d\tau]_{\alpha_1} \quad [8A]$$

$$\text{or } S_{\lambda 1} = [dR_{(\lambda)}/dn \, dk \, d\tau]_{\lambda_1} \quad [8B]$$

respectively. As can be seen from the explicit function of R given by the characteristic matrix of a thin film assembly, the reflectance is not only a function of the optical parameters of the sensing layer, but also depends on the optical parameters of the incident and emerging media, as well as those of the metal film that generates the surface plasmons. In addition, the refractive indices and extinction coefficients of these media are related to one another by the complex form of Snell's Law, which complicates the function R even further. In general, however, changes in the experimental value of R are generated by two factors: the shift of the position and the change of the shape of the resonance spectrum. The latter parameter is usually described either by the sharpness of the SPR spectrum, i.e. its half-width, or by the slope of the reflectance function, and characterizes the resolution in either the resonance angle or the resonance wavelength.

Both of these factors affecting sensitivity are dependent upon the field distributions within the resonant structure. The extent of the resonance angle shift is dependent upon the fraction of the resonant mode that lies within the sensing layer; the higher the fraction, the greater the sensitivity. This is why tight confinement of the surface plasmon evanescent wave to the sensing layer, which results in maximizing the fraction of the evanescent field in this region, favours high sensitivity. The resolution in the resonance angle (or wavelength) shift (setting aside instrumental considerations) is determined by the width of the resonance, which is defined by the losses of electromagnetic field energy within the system. The absorption by the metallic layer is the dominant factor in the SPR spectral width. Scattering of the electromagnetic wave causes further losses and increases with increased irregularities in the film structure and surface roughness, and with lower exciting wavelengths.

In summary, the overall sensitivity of the SPR device depends on both the metallic layer material (e.g. gold or silver), and the type of surface plasmon resonance being measured. The increase in the evanescent field is much smaller (about 2-fold) with gold than silver, which translates into about a 4-fold smaller overall sensitivity for an SPR device based on gold. On the other hand, gold layers are usually more stable in practical use than are silver films. The different types of surface plasmon resonances show different distributions of the evanescent electromagnetic field within the resonator device resulting in widely varying sensitivities. Long-range surface plasmon resonance has about 2.5-fold higher overall sensitivity than conventional SPR, whereas CPWR shows an even higher increase in sensitivity: about 3.5-fold (for *p*-polarization) and about 8-fold for *s*-polarization, as compared to conventional SPR. Therefore, the final design of an SPR device is usually a compromise between the different factors influencing overall sensitivity, durability, and any other requirements of the device for a specific practical application.

In view of its simple instrumentation and its high surface sensitivity, surface plasmon resonance (SPR) and, more recently, SPR microscopy gains an increasing significance to numerous problems concerned with the study of interactions occurring near to or at surfaces. Applications can be found in the optical behaviour of metals, the study of Langmuir–Blodgett films and self-assembled monolayers, the interactions of proteins with interfaces, or redox reactions at interfaces. A fast-increasing field is the development of sensitive chemo-optical sensors, intended to quantitatively and selectively monitor the presence of pre-specified and chemical species, which can be in the range from a molecular mass of ~ 200 Da to 150 kDa. The main reason for the high sensitivity of SPR to surface phenomena should be attributed to the high local electromagnetic field strengths brought about by surface plasmons (SPs).

Several excellent monographs have been published on SPR theory, whereas an overview on applications is the subject of another article in this Encyclopedia. This chapter will be concerned with experimental techniques for a variety of SPR applications.

Basic Requirements

Although SPs can be excited in an electron beam, we will only consider the common case where they are generated by means of light.

SPs can be excited in any material where free charge carriers exist; in the majority of practical cases this means that a metal layer deposited on a dielectric material is used as a medium to carry SPs. It turns out that the particular SP properties strongly depend on the nature of this

deposited layer: if the metal is present as an island-like structure with patches of the order of a few tens of a nm, *radiative* plasmons will be excited resulting in large enhancements of the applied (optical) field strengths. This effect is mainly used to enhance surface responses in vibrational spectroscopy, such as Raman and infrared spectroscopy. *Nonradiative* SPs can be excited if the metal layer is applied as a thin (~ 50 nm) homogeneous layer. These plasmons have the peculiar property that the associated electromagnetic field is evanescent in character, i.e. the wave vector k_x parallel to the interface is (partly) real, whereas that perpendicular to the interface is imaginary. The generation of SPs is an elastic scattering process, implying that both energy and momentum are conserved. Consider the system as depicted in **Figure 1a**, where a metal layer is sandwiched between two media a and p, which is the commonly used Kretschmann configuration. In view of Snell's law, which states that through this whole system k_x remains constant, this has the consequence that SPs can only be excited at the interface a/m when light enters the metal layer through another interface m/p, *under the condition that* $\varepsilon_p > \varepsilon_a$, where ε_p and ε_a denote the respective dielectric constants. This is further illustrated in **Figure 1b** where the two lines a and p represent the light dispersion relations in the media a and p, respectively, and the curve represents the SP dispersion relation. A further necessary condition is that the exciting light has to be p-polarized, because light polarized along the metal interface cannot exist.

This short theoretical description contains all the information needed for setting up a basic SPR experiment.

Choice of Metal Support

An approximate expression for the SPR wave vector can be found in the literature:

$$k_x = (2\pi/\lambda)(\varepsilon_m \cdot \varepsilon_a / (\varepsilon_a + \varepsilon_m))^{1/2} \quad [1]$$

where λ is the wavelength *in vacuo*, and ε_m is the metal dielectric constant at the wavelength used. Generally, k_x of the incoming light can be adapted to that required by eqn [1] by inclining the beam relative to the interface normal. The following relation holds (see also **Figure 1a**):

$$k_x = (2\pi/\lambda) \cdot \varepsilon_p^{1/2} \cdot \sin \theta \quad [2]$$

Figure 1 The SPR experiment. (a) a metal layer m is sandwiched between two dielectric media a and p . The direction x is defined parallel to the layer structure; (b) dispersion relation of SPs; see text; (c) a typical SPR curve when medium a has a refractive index $n_a = 1$. The angle θ_{cr} corresponds to the critical angle for the a/p interface.

However, in practice the maximum angle θ that can be chosen is around 80° , implying that in a number of cases the dielectric constant of the support, ϵ_p , has to be selected such that within this material a light beam can have a *practical* k_x matching that of eqn [1]. If medium a is a water solution (refractive index $n_a \sim 1.33$; note that $n = \epsilon^{1/2}$) then BK7 glass ($n_p \sim 1.52$) is an appropriate material. For media with higher refractive index SF10 glass ($n_p \sim 1.7$) can be used. (The abbreviations BK7 and SF10 refer to a nomenclature common in lens-making technology.) Convenient shapes of the dielectric support are prisms with apex angle 60 degrees or hemicylinders, which minimize the reflection loss of light when entering the support (cf. **Figure 1a**).

Choice of Metal Layer

A typical application of SPR spectroscopy is to monitor a layer growth on the metal layer. Such a process can be modelled as a changing ϵ_a , which experimentally translates into a changing resonance angle θ_{SPR} . **Figure 1c** depicts a reflectance curve obtained from a SPR experiment. From the figure it is clear that in order to obtain maximum sensitivity to variation in ϵ_a the slope $dR/d\theta$ has to be as large as possible. For a given ϵ_a this depends in a complicated way both on the value of $\epsilon_m(\lambda)$ and on the thickness of the metal layer. Generally, it can be said that smaller real and imaginary parts, $\text{Re}(\epsilon_m)$ and $\text{Im}(\epsilon_m)$, result in smaller resonance halfwidths, whereas the metal layer thickness is an important parameter determining the minimum reflectance. From **Table 1**, which gives an impression of $\epsilon_m(\lambda)$ for some metals, it can be concluded that in the visible wavelength range silver is expected to exhibit the narrowest resonances. This is indeed found experimentally; however, in many situations where experiments are performed in a water or air environment, silver tends to undergo unwanted interactions with its environment, making this a less attractive material. In this respect gold is a much more stable

Table 1 Real and imaginary parts of dielectric constant for some metals

Metal	λ (nm)	ϵ_{re}	ϵ_{im}
Aluminium	600	-29.8	7
	700	-46.6	22
	900	-55.5	30
Silver	500	-8.23	0.3
	700	-21.3	0.7
	900	-38.7	1.3
Gold	600	-8.37	1.2
	750	-18.2	1.2
	900	-28.5	1.8

material and thus this material has become the standard metal for SPR purposes, despite its resonance width that at $\lambda = 633$ nm is approximately three times larger than that of silver.

For a given metal the optimum layer thickness depends on the wavelength used, as illustrated in **Figure 2**; also the remarks on the importance of the value of $\epsilon_m(\lambda)$ are apparent from the figure. For any wavelength within the visible range a gold or silver layer thickness can be found corresponding to a vanishing minimum reflectance; for the often used helium-neon laser wavelength $\lambda = 633$ nm this is approximately 47 nm for gold and 49 nm for silver.

Practical Aspects

As already mentioned, in order to be able to excite non-radiative SPs it is important to have available smooth, homogeneous metal layers with a well-defined layer thickness. An appropriate way to prepare these is to sputter or to evaporate the metal at a high rate (~ 1 nm s^{-1}) in a vacuum chamber (10^{-6} mbar) on the substrate of choice. In order to increase the adhesion between metal and underlying dielectric, the support is often precoated with a 2 nm Ti or Cr layer. It is not mandatory to coat directly on the prism; alternatively, a flat substrate, such as a microscope glass cover slip, can be used as a substrate.

Figure 2 SPR reflectance curves for a bare gold layer with thickness 44 nm, measured with different wavelengths: (a) 676 nm; (b) 647 nm; (c) 633 nm; (d) 568 nm; (e) 514 nm; (f) 488 nm.

After coating, this plate is optically connected to the prism using a matching oil; care has to be taken that, in order to avoid spurious reflections, plate, oil and prism have the same refractive index in the wavelength region of interest.

Although a simple incandescent light source can be used for SPR, the use of a small HeNe or diode laser is far more convenient, in view of their well-defined wavelength and high degree of collimation.

SPR Instrumentation

Rotation Stage

The most straightforward method to measure SPs is depicted in **Figure 3**, where the prism/gold assembly is placed on top of a rotation stage (angular resolution typically 0.01 degree). With such an arrangement, all the features of a SPR curve can be accurately determined. The light detectors consist of simple large area photodiodes whose output is fed into a low-noise current-to-voltage amplifier. The excitation laser beam is polarized such that both s- and p-polarized light enter the prism. The use of a polarizing beamsplitter serves two purposes: one detector measures only the reflected s-polarized light whose intensity is only affected by laser intensity fluctuations and angular dependent refraction losses, whereas the other detector in addition measures SPR effects. The ratio between the two outputs then provides a signal proportional to the net SPR response. In order to obtain an absolute angular read-out with sufficient accuracy the critical angle can be measured; this angle is very accurately known for a certain ϵ_p/ϵ_a interface, and is an easily discernible feature in a SPR curve (cf. **Figure 1c**).

The obvious disadvantage of this setup is that it is difficult to monitor fast changes in the SPR curve. To be able to monitor time-dependent changes, the orientation

Figure 3 Rotation stage SPR setup. d: detectors; PBS; polarizing beamsplitter.

of the rotation stage relative to the light beam is often set such that the reflectance is about halfway between maximum and minimum. A changing ϵ_a is then approximately linear in the monitored changed reflectance. However, one has to assume that a change of ϵ_a leaves the width of the SPR curve unchanged.

Use of a Focused Beam

A more elaborate setup is shown in **Figure 4**. Here, SPs are excited by a focused diode laser beam such that the beam waist is slightly displaced from the top metal/dielectric interface. In this way, a certain distribution of angles is present at the interface. The reflected beam is imaged onto an array consisting of a large number (50–100) of photodiodes. The angular range corresponding to resonance will exhibit a low intensity; consequently, the output of the diode array is a measure of the angular dependent reflectance. Although the distance between individual diodes is relatively large ($\sim 20 \mu\text{m}$), the use of numerical interpolation techniques makes it possible to obtain an angular resolution of ~ 1 millidegree. Because no moving parts are involved, this system is capable of monitoring relatively fast-changing SPR characteristics: the temporal resolution will now be determined by the read-out rate of the diode array. A drawback of this system is that obtaining an *absolute* angular read-out is not as straightforward as in the case of the rotation stage, in view of the limited angular range that is applied to the metal/dielectric interface.

Photothermal Detection

When a nonradiative SP decays it generates heat at the metal/dielectric interface. This observation can be fruitfully exploited to detect the presence of SPs. In a

Figure 4 Use of focused beam. a: laser diode; b: focusing optics; c: neutral density filter; d: diode array. A flow cuvette is placed on top of the metal layer. Reproduced with permission from Sjölander S (1991) *Analytical Chemistry* 63: 2338. © American Chemical Society.

Figure 5 Basic photothermal detection setup. The position of the deflected beam of a probe laser PL is measured by a position-sensitive detector PSD.

photoacoustic approach, the prism/metal assembly is placed in an airtight chamber. SPs are excited with an intensity-modulated light beam; the resulting periodic heat flow from metal to dielectric as a result of plasmon decay causes a periodic pressure variation in the dielectric which can be detected by a microphone in the sample chamber. A significant difference as compared with optical detection is that SPR is now detected as a *maximum* in response. This method is mainly used in fundamental studies where one is interested in SP decay. The method is less suited in situations where the dielectric of interest consists of a fluid, such as water.

In a related approach, the heat flow is detected optically (*photothermal deflection spectroscopy*). A representative setup is shown in **Figure 5**. The prism/metal assembly is placed upon a rotation stage, and SPs are excited in the usual way. Heat produced by the decaying plasmon results in a gradient of the refractive index immediately above the metal layer. Consequently, the propagation direction of the light beam of the probe laser will be deflected and this can be measured, e.g. by using a position-sensitive detector. By modulating the SPR excitation beam and synchronous detection of the detector output, a differential signal is obtained whose angular dependence is directly related to the SPR curve. Using a

Figure 6 Vibrating mirror setup. Reproduced with permission from Lenferink ATM (1991) *Sensors and Actuators B (Chemical)* 3: 261. Copyright 1991, with kind permission from Elsevier Science Ltd, The Boulevard, Langford Lane, Kidlington, OX5 1GB, UK.

HeNe laser as the excitation source an angular resolution of ~ 0.01 degree can be obtained; contrary to the setups where the reflectance is measured, this resolution can be improved by employing higher laser powers. It has been demonstrated that this deflection method is also useful in water solutions.

Sensor Configurations

As already mentioned, an important application of SPR is in the field of chemical sensors. Such a SPR sensor system should be simple, compact, and relatively inexpensive, while retaining the angular sensitivity. Some representative SPR sensor systems will now be discussed.

Vibrating Mirror Device

In the system as depicted in **Figure 6** the angle under which the light from a laser diode enters the interface is made time-dependent by means of a mirror, vibrating at a frequency of ~ 50 Hz. If the optical system in the excitation path is designed properly, the light spot during an angular scan of ~ 5 degrees is stationary on the interface to within 0.2 mm, while the beam divergence is kept within 0.02 degrees. Although this setup can be used to monitor the complete SPR curve, it is dedicated to determine only the angle of minimum reflectance θ_{SPR} , which for the majority of SPR applications is the main parameter of interest. This can be conveniently accomplished as follows: during one cycle of the vibrating mirror the beam traverses the reflectance minimum twice. The time span Δt between these two minima is measured using appropriate electronics. If θ_{SPR} changes, Δt changes accordingly. Connected to a personal computer, this provides a versatile means to detect a SPR minimum with an angular resolution of 1 milli-degree. The time resolution of such a setup will be determined by the vibration frequency of the mirror. (Note that

vibrating mirrors operating at frequencies up to 10 kHz are available.) For some applications the difficulty of obtaining an absolute angular read-out will be a disadvantage.

Use of Diffraction Gratings

In the foregoing configurations a SP was excited using a prism. However, plasmons can also directly be produced on a grating surface coated with a thin metal layer. The condition for SPR to occur is determined by the grating periodicity (typical value $2000 \text{ lines mm}^{-1}$) and the angle of incidence of the light beam, whereas the value of the reflectance minimum is solely determined by the grating depth (optimum value $\sim 50 \text{ nm}$). Any of the above described setups can be used to detect SPs in this configuration. An advantage of this approach is that gold-coated gratings can be very easily and inexpensively manufactured as disposable replicas, once a holographic master grating has been produced. An important disadvantage is that the light beam has to enter the dielectric/metal interface from the dielectric side, implying that this is only a valuable approach for transparent media.

Fibre-Optic Devices

In situations where the sensing surface should be remote from the signal processing equipment (such as in a hostile environment or in a living organism) the use of optical fibres can provide a practical solution. Apart from the trivial use of a fibre to transport the light to and from a separate prism/metal assembly, it has also been demonstrated that the fibre can also be used as an *intrinsic* sensing interface, where part of the fibre surface replaces the prism. This concept is schematically shown in Figure 7. Light is fed into a fibre connected to an optical splitter/combiner S. The output port 1 of S is connected to a probe fibre, which is decladded at the distal end. After interaction with this end interface (see below) the light is reflected and again enters S, where it is transmitted to output port 2. A fibre connected to this port transports the light to a detector.

Several possibilities exist for the design of the decladded fibre tip. In Figure 7a the tip of a monomode fibre is cleaved at a specific angle and is subsequently coated with a metal layer of appropriate thickness. As the wave vector (cf. eqn [2]) of the propagating light in a monomode fibre is well defined the cleaving angle can be calculated such that excitation of SPs is possible in the ϵ_a region of interest. Again, SP excitation is detected by a decreased reflected intensity. In order to obtain optimum response it is advisable to use polarization-preserving fibres. In Figure 7b another approach is depicted, involving the use of a multimode fibre. Here, the circumference of the tip is metal coated; additionally a mirror is deposited on the distal end to minimize reflection losses. For a multimode fibre a (discrete) range of wave vectors simultaneously propagates; in order to be able to detect

Figure 7 Use of fibre optics. L: light source; D: detector; S: fibre splitter/combiner; 1, 2: output ports. (a): single mode fibre; (b): multimode fibre (cf. text).

changing characteristics of the metal/dielectric interface it is therefore necessary to use a broadband light source. The SPR information will now be contained in the wavelength-dependent reflectance. An advantage over the monomode configuration is that a broader range of SP wavevectors can be excited.

SPR Microscopy

The foregoing discussion has ignored the possibility to obtain spatially resolved information from a SPR experiment. However, it is known that SPs are collective electron oscillations *with a limited coherence length* L_x , implying that two regions in the metal with a mutual distance larger than L_x are capable of supporting SPs which are mutually independent. This phenomenon can be exploited to image structures on top of a metal layer that have a distribution of different ϵ_a : if the angle of light incidence is such that one particular ϵ_a corresponds to resonance, then regions with another ϵ_a will exhibit larger reflectance. An example of such an experiment can be seen in Figure 8, where the spatially resolved reflectance of an inhomogeneous monomolecular layer, consisting of molecules oriented either tilted or perpendicularly to the surface is depicted.

Of course, in such an experiment one aims to obtain maximum lateral resolution, while retaining the vertical (thickness) resolution. A general rule is that L_x decreases for increasing resonance halfwidths (cf. Figure 1c). However, as was pointed out in an earlier section, such an increasing SPR halfwidth simultaneously deteriorates

Figure 8 SP microscopic image of an inhomogeneous monolayer. Dimensions of image $0.2 \times 0.2 \text{ mm}^2$. Thickness difference of the two types of domains is less than 0.4 nm. Lateral resolution approximately $3 \mu\text{m}$.

vertical resolution. Therefore, for each particular situation a balance has to be sought between these two contradictory conditions. This is exemplified in **Figure 9** where SPR results are shown of a 2.5 nm SiO_2 ridge on gold for various wavelengths. It is clearly seen that at the shortest wavelength used the lateral resolution is the highest ($\sim 2 \mu\text{m}$), but the slope is the lowest (compare also **Figure 2**), indicating that it is difficult to obtain sufficient intensity contrast to detect sub-nm height differences, which is usually not a problem with standard SPR experiments.

Instrumentation

The first SPR microscopy experiments were done using a scanning focused beam. However, a straightforward approach, by imaging a collimated beam, proved to be much faster and instrumentally much simpler while both the lateral and vertical resolution are comparable or better. Therefore, only this last approach will be discussed in more detail.

Figure 10 gives an overview of a representative setup. A prism/gold layer assembly and an optional cuvet system are placed on a rotation stage (angular increments 0.01 degree). SPs can be excited using light from a HeNe or an argon/krypton ion laser. This last light source has the advantage of providing a large number of high power wavelengths over the whole visible range. After having passed through a Pockels cell and a spatial filter, the light spot entering the prism has an area of $\sim 1 \text{ cm}^2$. The intensity profile of the reflected beam is recorded with a

Figure 9 Lateral resolution in SPR microscopy. The vertical lines denote the physical width of a 2.5 nm SiO_2 ridge. Number insets correspond to the various wavelengths used.

microscope consisting of an objective and CCD video camera. It is important that the video camera has a response linear in the light intensity (see below). Depending on the light intensity and required magnification, objectives with focal distances between 5 and 50 mm are used. The Pockels cell and rotation stage are controlled by a microcomputer and the obtained images are also stored in this same computer by using a frame-grabber card.

It also proves possible to use the aforementioned gratings in a SPR microscopic experiment. Rotation of such a plate about the normal is equivalent to changing the angle of incidence of the exciting light. Compared to the standard prism setup this configuration is very compact and can easily be integrated in a conventional light microscope.

Improvement of Image Quality

Apart from the diffraction limit of the use of imaging lens there are a number of factors determining the eventual quality of a SPR microscopy image. As already mentioned, the use of shorter wavelengths generally improves lateral resolution, but simultaneously results in lower intensity contrasts for a given height difference. With such relatively low contrasts the use of a digital frame-grabber (which has a typical dynamic range of 2^8) can result in *quantization effects during image acquisition*, which become apparent if a low-contrast image is digitally amplified. To avoid this effect an option is to add a number of images with an effective dynamic range substantially larger than that of the frame-grabber used.

Integrating a number of images also results in averaging. This can be particularly important if shot noise is present when working with low light levels. Such an averaging will result in a signal-to-noise (SNR) improvement with a factor of $n^{1/2}$ where n is the number of added images. Another possible way to increase SNR is to increase laser power but this option is of limited value in view of the resulting destructive heating effects on the sample.

Another experimental problem is *lateral nonhomogeneity of the incoming laser beam intensity profile*. This can be partially solved by spatial filtering as indicated in **Figure 10**; however, if there are any unwanted, spurious reflections in the light path between the spatial filter and CCD camera, then again a beam nonhomogeneity will occur owing to the relatively large coherence length of the laser light used. An appropriate method is the use of a Pockels cell with simultaneous digital image processing. Such a cell can be configured such that the application of a voltage results in transmission of either p- or s-polarized light, without moving any part in the light beam. In the SPR microscope the Pockels cell is employed to acquire two images using p- and s-polarized light, respectively. The image with p-polarization contains the SPR

Figure 12 Scheme of a combined SP microscope and a scanning probe microscope. The tip can either be a STM or an AFM tip. Reproduced with permission from Specht M (1992) *Physical Review Letters* 68: 476–479. American Physical Society.

microscopic image together with the contrast generated by spatial nonhomogeneities, whereas the image obtained with s-polarization only contains the same unwanted nonhomogeneities. Because the CCD camera output is linear in intensity, the ratio of the two images is a true representation of the SPR-related reflectance variations over the imaged surface. An example of the result of such an approach can be seen in **Figure 11**. Although lateral nonhomogeneities are still visible in the ratioed SPR image, the resolution is approximately $2\ \mu\text{m}$; for this image the difference in reflectance between the two regions is ~ 0.01 .

Combination with Other Microscopies

Since the birth of scanning probe microscopy several attempts have been undertaken to merge this approach with SP microscopy. In **Figure 12** a schematic diagram is given where a SPR microscope is combined with a scanning tunnelling microscope (STM). The hemisphere, serving as a prism, is metal-coated, and SPs are excited in

the usual way. The metallic STM tip is brought close to the surface (distance $\sim 5\ \text{nm}$). The area of interaction between the tip and the surface is imaged on a photodiode. The tip is allowed to scan laterally over the surface and the photodiode output is monitored simultaneously. It was found that small corrugations on the surface which were detected by the tunnelling current of the STM were equally well monitored by the SPR reflectance. In this way a lateral resolution of $\sim 5\ \text{nm}$ could be demonstrated in a SPR image. Similar conclusions could be made for a dielectric atomic force microscopy (AFM) tip. Even better results can be obtained if the conically scattered SPR radiation is monitored rather than the specularly reflected light.

A discussion on the contrast mechanism in both setups is far beyond the scope of the present article; a pragmatic remark is that, in most cases, an AFM type tip is preferable in view of the fact that in the latter case no conductivity conditions have to be imposed on the samples of interest.

ω	frequency of surface plasmon wave

The physics of surface plasmons propagating along a metal/dielectric interface has been studied intensively, and their fundamental properties have been found to be in good agreement with theoretical concepts based upon the plasma formulation of Maxwell's theory of electromagnetism. The phenomenon has been utilized extensively by physical scientists in studies of the properties of surfaces and thin films. Current interest in the properties of thin surface coatings stems partly from increased applications to thin film devices and, in particular, to developments in biosensor devices. This article focuses on the characterization of the surface plasmon resonance phenomenon, with emphasis on the conditions of optical

excitation of plasmon resonance and the theoretical analysis of different types of surface resonances.

Description of Surface Plasmons

The concept of surface plasmons originates from the plasma formulation of Maxwell's theory, where the free electrons of a metal (or a conductive electron gas) are treated as a high density liquid (plasma). Plasma oscillations in metals are collective longitudinal excitations of the conductive electron gas, and plasmons are the quanta representing these charge-density oscillations. Such oscillations can exist in the bulk media, and can also be localized on an interface between a metallic and a dielectric surface, along which they propagate as waves. In the latter case they are called surface plasmons (SP), or surface polaritons. The spreading electron density fluctuations generate a surface-localized electromagnetic wave which propagates along the plane interface between the metal/dielectric media, with the electric field normal to this interface and vanishing exponentially with penetration distance from the interface. These characteristics of the electromagnetic field are the same as those describing the guided surface waves (also known as evanescent waves) generated optically under total internal reflection conditions when all the incident light is reflected at the boundary of the incident and emerging media. Under such conditions the electric and magnetic fields do not, however, stop abruptly at the boundary. Rather they penetrate a distance into the emerging medium in the form of a surface wave. Although the existence of guided surface electromagnetic waves has been theoretically predicted from Maxwell's equations and investigated during the first decade of the 20th century, it is only since 1960 that they have attracted the interest of the experimentalist and the term 'surface plasmon' has been used. This is partly due to the fact that methods have been developed which enable the optical excitation and detection of surface-bound electromagnetic waves (see below).

It has been shown that Maxwell's equations have solutions resulting in the generation of surface plasmon electromagnetic waves only when the following conditions are fulfilled: (1) one of the adjacent media (i.e. the surface active medium which generates surface plasmon

waves) has a negative value for the real part of its complex dielectric constant ϵ , and (2) a component of the wave vector along the interface between these two media, K , satisfies an equation which involves the dielectric constants of both media. These conditions are discussed in more detail in the following sections.

Optical Excitation of Surface Plasmons

The condition that the surface active medium has a negative dielectric constant results in several experimental requirements which have to be fulfilled in order to be able to generate surface plasmon waves. First, not all materials can be utilized as surface active media; gold and silver are the best examples of materials which can support surface plasmons. In addition, the electromagnetic wave in the surface active medium is an evanescent wave under all circumstances. Therefore, in order to satisfy boundary conditions in the surface active and dielectric media, which require that the tangential components of the electrical and magnetical fields be continuous across the boundary (i.e. that a component of the wave vector along the interface must be the same in both media), surface plasmons can only be optically generated by an evanescent wave whose wave vector matches that of the evanescent surface plasmon electromagnetic wave K_{SP} . The latter is given by the following equation:

$$K_{SP} = \omega/c(\epsilon_1\epsilon_2/(\epsilon_1 + \epsilon_2))^{1/2} \quad [1]$$

where ω is the frequency of the surface plasmon wave, c is the velocity of light *in vacuo*, and ϵ_1 and ϵ_2 are the complex dielectric constants for the surface active and dielectric (emerging) media, respectively. The complex dielectric constant ϵ is directly related to the complex index of refraction $N=c/v=n-ik$, by the following relation:

$$\epsilon = \epsilon' + i\epsilon'' = N^2 \quad [2]$$

where the real part of the complex dielectric constant is $\epsilon' = n^2 - k^2$ and the imaginary part is $\epsilon'' = 2nk$, n is the refractive index, k is the extinction coefficient, and v is the velocity of light in the dielectric medium.

These constraints require that surface plasmons cannot be directly excited by incident light, and produce a resonance condition for the wave vector of the evanescent wave which excites the plasmons. Furthermore, indirect SP excitation can only be achieved by an evanescent wave generated by p-polarized incident light under total internal reflection conditions. This occurs when a beam of light propagating through an incident medium (e.g. a prism) of higher refractive index (n_0) meets an interface with a second (emerging) medium of

lower refractive index (n_2) at incident angles α larger than the critical angle for total reflection α_c , given by $\alpha_c = \sin^{-1}(n_2/n_0)$. Since the prism has a dielectric constant, $\epsilon_0 = n_0^2$ (i.e. $k_0 = 0$) the following relation must be satisfied: $\epsilon_0 > \epsilon_2$ (or $n_0 > n_2$), where ϵ_2 is the dielectric constant and n_2 is the refractive index of the emergent dielectric medium. Although metal-coated diffraction gratings may be used instead of prisms, they require a greater complexity of fabrication without additional benefits, and so they have not been widely used and will not be discussed further.

Despite being totally reflected, the incident beam generates an evanescent electromagnetic field that penetrates a small distance, the order of a wavelength, into the second medium, where it propagates parallel to the plane of the interface. This electromagnetic field can be used to measure the optical properties of interfaces and thin films in various ways. The two main types of applications of optically generated evanescent waves are those based on waveguiding systems, and those used to excite surface plasmon resonance (SPR).

In waveguiding techniques the measured interface (or thin film) is placed in the evanescent region of a guided mode propagating in a dielectric waveguide structure. The optical properties of the interface (or thin film) affect the propagation characteristics of the evanescent surface wave causing changes in the resonant waveguide mode. These changes can be measured by a variety of optical techniques including attenuated total reflection (ATR) spectroscopy, total internal reflectance fluorescence (TIRF), where the evanescent wave is employed to excite fluorescence from molecules in the interface, or interferometry.

In order to generate SPR using an evanescent wave which is produced during an internal total reflection of the light from a prism whose base is coated with a thin metal film, the following two conditions have to be fulfilled. First, a component of the incident light vector parallel to the prism/metal interface, K_{ph} which is described by the following equation:

$$K_{ph} = (\omega/c)\epsilon_0^{1/2} \sin \alpha \quad [3]$$

must be identical with the surface plasmon wave vector, K_{SP} (see eqn [1]):

$$K_{ph} = K_{SP} \quad [4]$$

The value of K_{ph} can be adjusted to match that of the surface plasmon wave by changing either ω , i.e. the frequency (or wavelength) of the excitation light, or α , i.e. the incident angle (see eqn [3]). Second, because the oscillations of the free electrons in a metal film can only occur along the normal to the plane of the metal surface, only p- (or TM, transverse magnetic) polarization of the

incident light is effective in generating surface plasmons. At the resonance condition (eqn [4]), the incident light is coupled into a SP wave travelling along and bound to the outer active (metal) surface, and the phenomenon is known as surface plasmon resonance (SPR). The SP wave is nonradiative, and can either decay into photons of the same frequency ω if coupling by the surface roughness takes place, or be converted to heat.

In practical terms there are two configurations, both based on the ATR technique available to optically excite SPR at the metal/dielectric (or emerging medium) interface. In the first, the Kretschmann configuration, the prism is in direct contact with the surface active (metal) medium. In the second, the Otto configuration, the prism is separated by a thin layer of a dielectric (inactive) medium at a distance of approximately one wavelength of excitation light from the metal film. The practical consequences of using these configurations to excite SPR are described below.

Analysis of Surface Plasmon Resonances Excited by Light

Although the SPR phenomenon can be accurately described in physical terms as propagating oscillations of free electrons at a metal surface, there is a simpler and more general approach which has been used to describe light propagation through optically anisotropic layered materials whose properties vary only along the layer normal. This is a standard mathematical tool used to describe the optical properties of multilayered thin-film devices, and the SPR phenomenon can be seen as a straightforward result of the application of such thin-film electromagnetic theory. The analysis applies Maxwell's equations to describe the propagation of a plane electromagnetic wave through a multilayer assembly of thin dielectric films, and is based on the following properties of the structure. The film is considered thin when the phase differences between the various waves in the assembly are constant with time. This condition invariably holds for films which have thicknesses of not more than a few wavelengths. A second requirement is that the thin-film materials are characterized by a complex refractive index, which in the optical region is numerically equal to the optical admittance in free space units. This is defined by the ratio of the total tangential electric (B) and magnetic (C) field amplitudes of the electromagnetic wave ($Y = C/B$). Additional constraints are that the tangential components of the electric and magnetic field vectors of the electromagnetic wave are continuous across the interface between any two thin films. Also, that in any thin film the amplitude reflection coefficient or reflectivity, sometimes known as the Fresnel reflection coefficient (r), defined as the ratio of the amplitudes of the

incident and reflected electric field vectors, at any plane within the layer is related to that at the edge of the layer remote from the incident wave, r_m , by $r = r_m e^{-2i\delta}$, where δ is the phase thickness of that part of the layer between the far boundary, m , and the plane in question. Solution of Maxwell's equations describing the propagation of a plane, monochromatic, linearly polarized, and homogeneous electromagnetic field within a multilayer thin-film assembly with the above mentioned attributes results in a relationship which connects the total tangential components of the electric and magnetic field amplitudes at the incident interface with the total tangential components of electric and magnetic field amplitudes which are transmitted through the final interface. This result is of prime importance in describing the optical properties of thin films and forms the basis of almost all calculations. It has the following standard matrix notation, known as the characteristic matrix of the assembly:

$$\begin{bmatrix} B \\ C \end{bmatrix} = \prod_{j=1}^s [M_j] \begin{bmatrix} 1 \\ Y_{j+1} \end{bmatrix} \quad [5]$$

where s is the number of layers deposited on the incident medium; Y_j gives the characteristic oblique admittance of the j th layer (Y_{j+1} for the emerging medium): $Y_j = Y_j / \cos \alpha_j = (n - ik)_j / \cos \alpha_j$ for p-polarized incident light, or $Y_j = Y_j \cos \alpha_j$ for an s-polarized electromagnetic wave, and M_j is known as the characteristic matrix of the j th thin layer and has the following form:

$$M_j = \begin{bmatrix} \cos \delta_j & i(\sin \delta_j)/Y_j \\ iY_j \sin \delta_j & \cos \delta_j \end{bmatrix} \quad [6]$$

where $\delta_j = (2\pi Y_j / \lambda) t_j \cos \alpha_j$ gives the phase thickness of layer j in the thin-film assembly; $(Y_0 \sin \alpha_0) = (Y_j \sin \alpha_j)$ is the complex Snell's Law which relates α_j to α_0 , the angle of incidence in the incident medium; t_j is the thickness of the j th layer; and α_0 and α_j are the incident angles of light of wavelength λ for the incident medium (a prism in the SPR system) and the j th layer, respectively.

There are two important conclusions which can be deduced from eqn [5]. First, the characteristic matrix of an assembly of j layers is simply the product of the individual matrices taken in the correct order. Second, sufficient information is included in eqns [5] and [6] to allow the full analysis of the electromagnetic field generated at each interface of a multilayer thin-film assembly, thereby yielding transmittance, absorbance, and reflectance for both p- and s-polarizations. Furthermore, the optical admittance presented at the incident interface by the system of layers and emerging medium is the product of the characteristic matrix of the assembly.

The optical admittance parameter has been introduced into thin-film optics with one specific aim, namely to visualize optical phenomena occurring within such

systems by means of a graphical representation of the optical events known as the admittance diagram. Although this is one of a class of diagrams known collectively as circle diagrams, it is particularly powerful and attractive and therefore it is used extensively in thin-film optics.

In the case of SPR which is generated optically with the ATR technique, the reflectance of a multilayer system, R , defined as the ratio of the energy reflected at the surface of such a structure to the energy which is incident, is an especially important parameter and can be calculated from the following relation:

$$R = rr^* \quad [7]$$

where:

$$r = (Y_0 B - C)/(Y_0 B + C) = (Y_0 - Y)/(Y_0 + Y) \quad [7a]$$

is the amplitude reflection coefficient (reflectivity or Fresnel reflection coefficient), and:

$$\begin{aligned} r^* &= \{(Y_0 B - C)/(Y_0 B + C)\}^* \\ &= \{(Y_0 - Y)/(Y_0 + Y)\}^* \end{aligned} \quad [7b]$$

is the complex conjugate of r . Y_0 is the admittance of the incident medium (which in the case of the present application to SPR is a non-light-absorbing glass prism, i.e. with $k=0$, and therefore the Y_0 value becomes real and equal to the refractive index of the incident medium, n_0).

Equations [5], [6], [7], [7a] and [7b] comprise a full set of mathematical tools to examine optically excited surface plasmon resonance. Such an analysis can be applied to the following three types of resonances (see the next section): (i) conventional surface plasmon resonance (SPR), (ii) the resonance associated with long-range surface plasmons (LRSPR), and (iii) the resonance associated with coupling of plasmon resonances in a thin metal film with waveguide modes in a dielectric overcoating, known as coupled plasmon waveguide resonance (CPWR). Although in all three cases the excitation of surface plasmons is based on coupling light photons to plasmons by the ATR technique, these resonance systems differ in their detailed thin-film structural designs, as described in the next section.

Variety of Surface Plasmon Resonances

Conventional Surface Plasmon Resonance

In the most straightforward case, for which the hypotenuse of the prism is coated with a single high-performance metal (Ag or Au) layer (Kretschmann coupling), one can generate surface plasmons on the outer surface of the metal, as indicated in **Figure 1**. This

shows this effect for either a 55 nm Ag or a 48 nm Au layer, as a consequence of an enormous increase in the intensity of the evanescent electromagnetic field, which is produced as a function of either the incident angle, α , with $\lambda = \lambda_0 = \text{constant}$ (panel a), or the wavelength, λ , with $\alpha = \alpha_0 = \text{constant}$ (panel b). This very large increase of electric field amplitude, as compared to that of the incident light, with the characteristics of a sharp resonance and which can only be obtained with p-polarized excitation light, is a result of a resonant generation of free metal electron oscillations, and is known as conventional surface plasmon resonance (SPR). As anticipated in the previous sections, **Figure 1** demonstrates the dependency of SPR on the optical parameters of the metal films, resulting in a much stronger evanescent electric field obtained with silver than with gold. The easiest means of experimental detection of this phenomenon is by measuring the changes in intensity of the totally reflected light (R) which has been used to generate plasmons in the ATR arrangement (**Figure 2**). In both cases, i.e. for R calculated either as a function of α with $\lambda = \lambda_0 = \text{constant}$ (**Figure 2a**), or as a function of λ with $\alpha = \alpha_0 = \text{constant}$ (**Figure 2b**), one obtains a resonance curve resembling in shape those shown in both panels of **Figure 1**. As demonstrated above, in conventional SPR the evanescent electromagnetic field reaches its maximum intensity on the outer metal surface and decays very rapidly with distance into the emerging dielectric medium. This effect is demonstrated in **Figure 3a**. In addition, **Figure 3b** illustrates the sensitivity of the SPR phenomenon to the thickness of the metal film.

Long-Range Surface Plasmon Resonance (LRSPR)

The second type of resonance, long-range surface plasmon resonance (LRSPR), is generated in the same way as conventional SPR, but uses a thinner metal layer which is surrounded by dielectric media that are beyond the critical angle so that they support evanescent waves. An example of a calculated LRSPR reflectance versus incident angle curve (**Figure 4a**) demonstrates a very narrow resonance (curve 1) as compared to conventional SPR (curve 2). The distribution of the resonantly generated evanescent electric field intensity along the normal to the film planes, presented in **Figure 4b**, clearly indicates two important differences between this type of resonance and conventional SPR: (1) LRSPR involves two surface bound waves on both the inner and outer surfaces of the metal layer; and (2) it is characterized by a much higher evanescent electric field at the outer metal surface, which results in a sharper resonance curve, as shown in **Figure 4a**.

Figure 1 Resonance spectra of the two most frequently used metal films, i.e. silver (solid line) and gold (dashed line), with the indicated optical parameters, presented as the total evanescent electric field amplitude (normalized at its largest value) generated by surface plasmons on the outer surface of the metal film, versus either the incident angle (α , panel a) obtained with p-polarized (transverse magnetic) light of constant wavelength ($\lambda = 632.8$ nm), or light wavelength (panel b) obtained at $\alpha = \alpha_0 = \text{constant}$. α_0 is the incident angle at which the resonance excited with light of $\lambda = \lambda_0 = \text{constant}$ reaches its maximum. The calculation has been done assuming a glass prism as an incident medium ($n_g = 1.5151$), and water as an emerging medium ($n_w = 1.33$), both at $\lambda = 632.8$ nm.

Figure 2 Reflectance SPR spectra, i.e. reflectance versus either the incident angle (α), with a constant value of the wavelength (λ_0) of the surface plasmon excitation light (panel a), or the wavelength, λ , at a constant value of α_0 (panel b), obtained with silver and gold films. Other experimental conditions and symbols are as in Figure 1.

Coupled Plasmon-Waveguide Resonance (CPWR)

The third type of surface resonance involves even more complex assemblies in which surface plasmon resonances

Figure 3 (a) Calculated amplitude of the evanescent electric field (normalized at its largest value) generated within a metallic film (shown by closed circles), obtained with both silver (solid line) and gold (dashed line) at constant values of α_0 , as a function of the distance from the glass prism/metal interface. (b) Influence of metal film thickness on the SPR spectra obtained with an excitation wavelength $\lambda_0 = 632.8$ nm for silver (solid line) and gold (dashed line) films. Other conditions as in Figure 1.

in a thin metal film are coupled with guided waves in a dielectric overcoating, resulting in excitation of both plasmon and waveguide resonances (CPWR). A coupled plasmon-waveguide resonator contains a metallic layer

(the same as in a conventional SPR assembly), which is deposited on either a prism or a grating and is overcoated with either a single dielectric layer or a system of dielectric layers, characterized by appropriate optical parameters so that the assembly is able to generate surface resonances upon excitation by both p- and s-polarized light components (Figure 5a). The addition of such a dielectric layer (or layers) to a conventional SPR assembly plays several important roles. First, it functions as an optical amplifier which significantly increases electromagnetic field intensities at the dielectric surface in comparison to conventional SPR, as illustrated by Figure 5b and 5c. This results in an increased sensitivity and spectral resolution (the latter due to decreased resonance line-widths, as shown in Figure 5a). Second, it enhances spectroscopic capabilities (due to excitation of resonances with both p- and s-polarized light components), which results in the ability to directly measure anisotropies in refractive index and optical absorption coefficient in a thin film adsorbed onto the surface of the overcoating. Third, the dielectric overcoating also serves as a mechanical and chemical shield for the thin metal layer in practical applications.

Coupled Long-Range Plasmon-Waveguide Resonance (CLRPWR)

This type of surface resonance can be obtained with a resonator which combines both the long-range surface plasmon and coupled plasmon-waveguide resonators into one device. The resulting resonance spectra are similar in shape and intensity to those obtained with CPWR devices.

Detection of Surface Plasmon Resonances

As discussed above, SP excitation generates surface electromagnetic modes bound to and propagating along the interface between a metal and a dielectric medium. Although these modes differ considerably from plane electromagnetic waves by having a pronounced dispersion (i.e. energy and momentum are not linearly connected by the speed of light), they demonstrate all other properties common to plane waves such as diffraction and interference. Therefore, the SP modes can, in principle, be detected by the same techniques as for plane electromagnetic waves, with two additional constraints, namely, that these are surface bound and are primarily nonradiative modes. Taking these special properties into account, together with the requirements which have to be fulfilled in order to excite SP modes, the most direct means of detecting these modes is by analysing the totally reflected light used to excite SPR.

The reflected light can be examined by analysis of either the transformation of light polarization using

Figure 4 (a) Calculated long-range SPR spectrum represented by reflectance versus incident angle (curve 1), obtained with p-polarized excitation light ($\lambda_0 = 632.8$ nm) and a glass prism coated with a MgF₂ layer (thickness = 965 nm, and refractive index = 1.379) on top of which a 32 nm thick silver film has been deposited. α_0 indicates the incident angle at which resonance achieves its maximum. The emerging medium is water with $n_w = 1.33$. Curve 2 illustrates the conventional SPR spectrum obtained with a 55 nm thick silver layer deposited directly on a glass prism (see **Figure 2a**). (b) Amplitude of the evanescent electric field (normalized to the largest value of the conventional SPR electric field as presented in **Figure 3a**) along the normal to the layer plane, calculated for the thin film design described in panel a and using $\lambda_0 = 632.8$ nm as an excitation wavelength at $\alpha = \alpha_0$ (see panel a).

ellipsometry techniques, or the alteration of light intensity by applying reflectometry methods. The state of polarization is characterized by the phase, δ , and amplitude, E_0 , of light polarized parallel (p-polarization) and normal (s-polarization) to the plane of incidence. The difference in polarization state between the incident and reflected light (denoted i and r, respectively) is described by the parameters ψ and Δ , which are defined as follows:

$$\tan \psi = (E_{0p}^r / E_{0s}^r) / (E_{0p}^i / E_{0s}^i) \quad [8]$$

$$\Delta = (\delta_p^r - \delta_s^r) - (\delta_p^i - \delta_s^i) \quad [9]$$

where $\tan \psi$ and Δ are the changes in the amplitude ratio and the phase difference, respectively, on reflection. The variables ψ and Δ often referred to as ellipsometrical angles are related to the ratio between the overall complex reflection (Fresnel) coefficients of the respective light components, r_p and r_s , by the following equation:

$$r_p / r_s = \tan \psi e^{i\Delta} \quad [10]$$

The Fresnel coefficients of the interface, r_p and r_s , can, with the aid of Maxwell's theory (as shown in the preceding section), be expressed as functions of the wavelength of the light, λ , the incident angle, α , and the optical properties of the reflecting system.

The reflectometry technique, which is based on measurement of reflected light intensity under ATR conditions, is experimentally a much simpler method than ellipsometry. It is therefore used much more frequently, especially in various sensor applications. As shown above, in this methodology, at a particular incident angle the light wave vector matches the wave vector of the plasmon, fulfilling resonance conditions for plasmon generation (see eqn [4]). During the resonance interaction, energy is transferred from photons to plasmons, so that the effect of plasmon excitation can be observed as a sharp minimum of the reflectance when either the angle of light incidence is varied at the same light wavelength, or the light wavelength is varied at the same incident angle, thus defining an SPR spectrum. In both instances, this spectrum reflects the resonance in absorption of incident photons.

Figure 5 (a) Coupled plasmon-waveguide resonance (CPWR) spectra presented as reflected light intensity versus incident angle, calculated with $\lambda_0 = 632.8$ nm as an excitation wavelength for both p- and s-polarizations, and a glass prism ($n_g = 1.5151$) coated with a 55 nm thick silver layer overcoated with a 460 nm SiO₂ film. The emerging medium is water ($n_w = 1.33$). The curve plotted with solid points illustrates the conventional SPR spectrum obtained with a 55 nm thick silver layer (see **Figure 2a**). α_0 indicates the incident angle at which the resonance achieves its maximum. (b) and (c) Amplitudes of the evanescent electric fields, as a function of the distance from the glass prism/metal interface, within a silver layer, an SiO₂ film, and the emerging medium for p- (panel b) and s- (panel c) polarized light of $\lambda_0 = 632.8$ nm, calculated at $\alpha = \alpha_0$ (see panel a), and normalized to the largest value of the conventional SPR electric field as shown in **Figure 3a**.

SPR can also be detected with a fluorescence technique known as total internal reflectance fluorescence (TIRF) employed with waveguided systems. The application of TIRF to monitor SPR is based on the following properties of the surface modes. First, there is a possibility that the nonradiative SP modes can, under specific conditions, decay into light, therefore allowing emission techniques to be utilized to detect the resonance. As noted above, nonradiative surface plasmons can decay into photons of the same frequency if coupling by the surface roughness takes place. The intensity of emitted light images the SPR occurring at silver and gold surfaces producing an emission resonance curve similar to that of the reflectance resonance curve obtained under ATR conditions. Secondly, the surface bound electric field generated by SP modes, which can be much higher than that of the plasmon excitation light (see **Figures 1, 3a, 4b, 5b and 5c**), can be used as an efficient source to excite fluorescence emission of molecules adsorbed at the SPR active surface. This property of the surface plasmon electromagnetic field allows the monitoring of resonance by using fluorescent labelling of molecules adsorbed (or immobilized) on the active surface of the SPR producing medium. In both cases the measurement of fluorescence emission intensity as a function of either incident angle, α , with excitation wavelength, $\lambda = \lambda_0 = \text{constant}$, or λ with $\alpha = \alpha_0 = \text{constant}$, will generate an excitation emission curve. Such an excitation emission resonance curve will reflect either the SPR absorption resonance spectrum, as usually measured with ATR (see above), or the combination of the absorption spectrum of a fluorescent label and the SPR phenomenon, for measurement of emission intensity versus λ , at $\alpha = \alpha_0 = \text{constant}$.

The investigation of surfaces, and of molecular layers adsorbed on surfaces, by electromagnetic radiation has been carried out principally by infrared spectroscopy. This is because of the high sensitivity of present-day Fourier transform infrared (FT-IR) spectrometers; the capability for IR spectroscopy to obtain data from mixed-phase samples with gas/solid, liquid/solid, or gas/liquid interfaces; and because of the availability of very large databases relating the positions and relative strengths of infrared absorptions to structural features of organic and inorganic molecules. As described below, the sampling techniques used differ substantially whether the systems under investigation involve finely divided samples (powders or porous solids) or whether the surface involved is flat. In the early history of the subject, spectral features relating to adsorbed layers and other surface phenomena could only be detected if very high area finely divided samples were used so that the radiation beam could pass through many interfaces. However, since the advent of FT-IR spectrometers, infrared sensitivity has so much improved that nowadays a measurable spectrum can be produced from even a single monolayer on a flat surface.

After reviewing the experimental techniques involved, we survey the principal applications of the infrared method under the headings surface characterization, physical adsorption, and chemisorption and catalysis.

Experimental Techniques

High-Area, Finely Divided, Surfaces

Surfaces, because of their unsaturated surface fields, normally require to be cleaned from contamination derived from the atmospheric environment before systematic research can be carried out on them. For finely divided samples of high area it is adequate to mount them in a high-vacuum enclosure ($\sim 10^{-6}$ mbar) provided with infrared-transparent windows and the means for treating the sample in oxygen or hydrogen at elevated temperatures. The samples themselves are most often studied in transmission, usually in the form of pressed discs derived from powders. These are prepared using a hydraulic press in a manner similar to that used for the standard potassium bromide pressed-disc sampling procedure for IR spectroscopy. The pressure required for

coherent disc formation is greater for the commonly studied oxide layers than for the softer potassium bromide, but the discs so prepared remain porous for adsorption studies. Alternatively, a powdered sample can often be made to cohere on an infrared-transparent disc, or on a fine metal grid, through sublimation or by deposition from a solvent.

Finely divided metal samples require that the opaque particles are separated from each other for transmission purposes. Usually this is done by distributing (supporting) them on the surface of an oxide which is transparent over relevant regions of the spectrum. Such samples are prepared by depositing metal salts from solution on the oxide particles followed by evaporation of the solvent; a disc is then pressed from the mixed powder and inserted in the IR vacuum cell; finally, the salt is reduced in hydrogen at appropriate temperatures so as to form metal particles distributed over the surface of the oxide support. Very high area powders of silica and alumina, of areas between 200 and 300 m² g⁻¹, are commercially available and are frequently used as metal supports. They have the advantages that they are largely infrared-transparent down to ~ 1300 or ~ 1100 cm⁻¹ respectively, and hence permit the study of many group-characteristic absorptions from organic adsorbates. Silica is a more catalytically inert support than alumina.

Samples prepared as described above can be good models for working catalysts of either the oxide or metal types and many infrared studies of surface phenomena are undertaken in conjunction with catalytic investigations. Loose powders can alternatively be studied by diffuse reflection, with the advantage for kinetic studies that surface reactions, rather than diffusion processes, are more likely to be rate determining than is the case with the fine-pored pressed discs.

Low-Area Flat Surfaces

Adsorbents in the form of flat surfaces are of very low area and normally ultra-high vacuum (UHV) conditions ($\sim 10^{-10}$ mbar) are required in order to preserve them from contamination. Where the substrate is transparent, infrared spectra of the surface layers can be obtained either by transmission or by reflection; when the substrate is non-transmitting, as in the case of metals, then reflection is normally used. Experiments involving flat

surfaces allow the application of polarized radiation for the purpose of obtaining information about the orientation of the adsorbed molecules with respect to the surface. For transparent substrates the use of radiation polarized in or perpendicular to the plane of incidence, in combination with the measured angle of incidence, can determine the direction of the dipole change with respect to the surface associated with each group-characteristic vibration. The orientations of even flexible molecules with respect to the surface can be deduced from such measurements.

In the case of metals the effect of the free response of the conduction-electrons to a charge above the surface can be modelled in terms of an image of opposite sign at the same distance below the surface as is shown in **Figure 1**. In the infrared context it is the dipole moment change associated with the vibration that interacts with the radiation. **Figure 1** shows that a component of such a dipole change that is parallel to the surface is cancelled out by its image, whereas a component perpendicular to the surface is doubled in magnitude. Hence only modes with perpendicular dipole components are IR allowed; in general these are those modes of vibration that are symmetrical with respect to all the symmetry elements associated with the surface complex. For example, a CO molecule adsorbed perpendicular with respect to the surface will give absorption bands from the ν_{CO} or ν_{CM} ($M = \text{metal}$) bond-stretching modes but not from the OCM bending modes. Such considerations constitute the metal surface selection rule (MSSR), which is widely used for the determination of molecular orientation or, if this is known, as an aid in the assignment of vibrational modes. For work with metals, reflection-absorption infrared spectroscopy (RAIRS) uses near-grazing incidence in order to maximize the strength of the electric vector of the incident infrared radiation that is perpendicular to the surface.

UHV is normally required when studying low-area flat surfaces (exceptionally this would not be a requirement if the adsorbate, such as a surfactant, is capable of displacing surface impurities) and this requires sophisticated

Figure 1 Charges and their images near metal surfaces; the origin of the metal surface selection rule (MSSR).

equipment. Also, the high sensitivity needed for the measurement of spectra from single monolayers requires the use of FT-IR spectrometers with selective photoconductive infrared detectors; the mercury/cadmium telluride detector which covers the major range of the spectrum down to $\sim 700 \text{ cm}^{-1}$ is widely used. **Figure 2** illustrates a typical experimental arrangement for RAIRS on a metal surface under UHV conditions. Spectroscopic work carried out on single crystals with known types of adsorption sites, such as are readily available for metals, are of great use in interpreting the more complex spectroscopic phenomena obtained from finely divided samples. Individual particles of the latter can exhibit facets with a variety of atomic arrangements and adsorption sites which can be studied one-at-a-time on single crystals.

Figure 3 The arrangements of atoms, and the resulting adsorption sites, on the (100), (111) and (110) surfaces of a face-centred-cubic metal.

Figure 3 shows the different atomic arrangements, and hence adsorption sites, of the (111), (100) and (110) faces of a face-centred cubic metallic lattice. UHV facilities also permit complementary spectroscopic methods involving particles such as electrons (as in high-resolution electron energy loss spectroscopy) or diffraction methods (as in low-energy electron diffraction) to be employed in order to characterize the same system further.

Adsorption on metal electrodes, which can be cleaned in solution by electrode reactions, is also studied by RAIRS. There is added interest in the effects of the variable electrode potential on the spectra and structures of the adsorbed species.

The surfaces of infrared-transparent materials that are available in the form of shaped and polished crystals, such as silicon or germanium, can be studied with good sensitivity by using attenuated total internal reflection (ATR) in conjunction with multiple reflection procedures.

Sum frequency generation (SFG) is a more recent spectroscopic development in which two laser beams, one in the visible region and the other of variable frequency in the infrared region, generate infrared-modulated signals in the visible region at the sum of the two frequencies. As the signals come only from the interface and not from the bulk, this technique is being exploited in high-pressure catalyst work and for surfactant research.

Surface Characterization

The long-range patterns of surface atomic arrangements are principally monitored by low-energy electron diffraction (LEED). Whereas in principle the top layers of a lattice have different frequencies and hence wavenumbers from those of the bulk lattice, the associated absorptions often fall within a spectral region dominated by the latter and are hence difficult to identify. Transition metal oxides are exceptional in that the variable valency associated with the metallic element can lead to the generation of surface $M=O$ groups (M = metal) that give absorptions of notably higher wavenumber than those of the lattice modes.

Infrared contributions to our knowledge of surfaces are mostly short-range in type and involve the identification of different types of site through the adsorption of probe molecules chosen for this purpose. CO is a well-known probe of surface sites on metal surfaces. As discussed in the Chemisorption section below, its νCO bond-stretching vibration has distinct wavenumber ranges for adsorption on linear (on-top), twofold and threefold bridging sites. Although linear and twofold sites can occur on each of the surfaces shown in **Figure 3**, the threefold one is specifically characteristic of (111) surfaces and can be used to identify such facets on metal particles. Distinctions can sometimes be made between twofold CO sites on different facets. The wavenumbers of CO absorptions can also be used to characterize surface cation sites of different charge (different formal oxidation states) on transition metal oxides as shown in **Figure 4** for a partially reduced Ni oxide sample. For hydrocarbon adsorption the characteristic spectrum of ethylidyne (CH_3C) also plays a useful role in identifying (111) facets on finely divided metals.

One of the earliest discoveries of surface infrared spectroscopy was that oxide surfaces, such as those of SiO_2 or Al_2O_3 , retain chemisorbed OH groups after the removal of water molecules adsorbed from the atmosphere. These can only be removed by high-temperature treatment and are presumably generated by the reaction of ambient water molecules with otherwise free valencies on the surface of the oxide lattice, according to the reaction $\text{O}^{2-} + \text{H}_2\text{O} \rightarrow 2\text{OH}^-$ or its covalent equivalent. In the case of alumina, for example, individual absorptions amongst a multiplicity of OH bond-stretching absorptions can be identified with linear, two- and threefold adsorption sites, for each of two types of surface aluminium atoms which in the bulk lattice have four- or sixfold coordinations, i.e. are in formal IV or VI oxidation states. Silica has only four silicon coordination and correspondingly a simpler νOH spectrum consisting mainly of absorptions of pairs of free and hydrogen-bonded OH groups on adjacent sites.

An acidic oxide such as alumina exhibits relatively inert OH groups, strongly acidic OH groups that are capable of proton donation (Brønsted acidity), plus aluminium ions that act as electron-deficient sites (Lewis acidity). The relative proportions of these on such oxide surfaces are analysed using the infrared spectrum of adsorbed pyridine. The spectra are measured in the $1700\text{--}1500\text{ cm}^{-1}$ region. Pyridine hydrogen-bonded to the weaker surface OHs gives a weakly perturbed spectrum; that interacting with the strongly acidic OHs forms the pyridinium ion by proton transfer which has a characteristic additional absorption at 1540 cm^{-1} ; that interacting with metal-coordination sites shows a change in wavenumber of a skeletal absorption near 1600 cm^{-1} .

Basic oxides frequently adsorb carbon dioxide from the atmosphere to give surface carbonates according to the reaction $\text{O}^{2-} + \text{CO}_2 \rightarrow \text{CO}_3^{2-}$, a process readily monitored by infrared spectroscopy. With the well-known exceptions of gold and platinum, metal surfaces adsorb oxygen from the atmosphere leading, in the cases of aluminium and iron, to the production of multilayer 'passivating' oxide films or (with the participation of absorbed water) thick films of rust, respectively. Infrared spectroscopy can monitor these surface corrosion processes.

Physical Adsorption

In this section we consider the spectroscopic study of the association of molecules with surfaces by intermolecular forces ranging from van der Waals to strong hydrogen bonding.

Figure 5 shows the absorption bands in the νCH bond-stretching region from methane adsorbed on porous silica glass. In the gas phase the triply degenerate νCH mode at 3019 cm^{-1} is infrared active and is to be

Figure 5 The IR spectrum of CH_4 adsorbed on high-area porous silica glass in the νCH bond-stretching region showing the presence of a gas-phase forbidden absorption. Reproduced with permission of the Royal Society from Sheppard N and Yates DJC (1956) *Proceedings of the Royal Society of London, Series A* 238: 69.

identified with the strong band from the adsorbed species at $\sim 3006\text{ cm}^{-1}$. On the surface an additional feature has appeared in the spectrum at 2899 cm^{-1} which is readily identified as the gas-phase forbidden νCH 'breathing' mode, known from gas-phase Raman spectroscopy to occur at 2917 cm^{-1} . The one-sided surface forces have distorted the original tetrahedral shape of the methane molecule so as to cause this mode to become active. The considerable breadth of the $\sim 3006\text{ cm}^{-1}$ absorption of the surface species, notably less than that of the gas-phase vibration-rotation band, was interpreted in terms of quasi-free rotation of the molecule about a single axis perpendicular to the silica surface.

The spectrum of **Figure 6** shows the interaction of the very acidic surface OH group on zeolite HY with adsorbed ethene. The low wavenumber, broad profile, and intensification of the shifted νOH absorption upon ethene adsorption indicate a hydrogen bond of considerable strength, comparable to that between water molecules, even although the bonding is only to the π -electrons of the adsorbed ethene. This complex is clearly an intermediate in the higher temperature formation of the carbenium ion C_2H_5^+ .

Hydrogen bonds are normally considered to form between acidic XH groups and electron-rich bases. However, surface infrared spectroscopy, in conjunction with HREELS, has shown that such bonds can also occur between electron-rich CH bonds of paraffins and electron-deficient sites on metal surfaces. **Figure 7** shows the spectrum of cyclohexane adsorbed on the (111) surface of platinum. The very broad band centred at $\sim 2620\text{ cm}^{-1}$ is from a proportion of CH bonds of the adsorbed cyclohexane in a hydrogen-bonded type of environment. As the separation between the three parallel axial CH bonds on one side of the cyclohexane molecule is almost exactly the separation between adjacent Pt atoms on a threefold site of the (111) surface, it is clear that the hydrogen bond is of the type $\text{CH} \cdots \text{Pt}$.

Figure 8 is a spectrum taken at 33 K in the νCH region of CD_3H adsorbed on the (100) face of the

face-centred-cubic lattice of NaCl. It is seen that there are two well-resolved absorption bands, one sharp and the other broad, resulting from CH bonds that are oriented differently with respect to the surface. One of these occurs with the incident light polarized in the plane of incidence but is eliminated when the light is polarized perpendicular to this; the other is present in both spectra. The former band hence has its νCH vibrational dipole change perpendicular to the surface, whereas the direction of the latter has both parallel and perpendicular components. Considerations of relative intensities, taking into account the angle of incidence, show that the broader low-wavenumber band is from CH bonds that are at $\sim 70^\circ$ with respect to the surface. It is hence concluded that the parent CH_4 molecules are adsorbed with three of their four CH bonds on the surface.

Even in the absence of the special effects of hydrogen bonding, bandwidths of 10 cm^{-1} or more are common from adsorbed species on polycrystalline substrates owing to interactions with sites that differ in their detailed environments. Absorptions obtained from adsorbed species on single-crystal planes with uniform and well-defined sites can, in contrast, be very sharp with bandwidths of less than 1 cm^{-1} . In the case of methane itself, and of a number of other molecules such as CO and CO_2 , the resolution of the spectra on alkali metal halide single-crystal surfaces is such that even the fine-structure splitting caused by the vibrational couplings of more than one molecule in the surface unit cell can readily be resolved.

Chemisorption and Catalysis

The quantitative and energetic aspects of the chemisorption of molecules on surfaces have long been investigated but, until in the 1950s it became possible to obtain infrared spectra, the actual structures of the surface species could only be a matter for speculation. The spectra show that in fact finely divided adsorbents give absorptions from several different surface species, and that the nature of the latter can vary as a function of coverage. Simpler spectra are obtained on single-crystal surfaces of known atomic arrangements. However, even so, the deductions of the structures of the chemisorbed species can be difficult because of uncertainties related to the effects of surface bonding on the spectra of the attached groups. The usual group-characteristic wave-number ranges can no longer be assumed to be reliable because of the electron-donating or -withdrawing properties of the surface atoms and also, when there is multiple bonding to the surface, because of strains associated with cyclic bonding features. The procedure adopted is to use the spectra to suggest possible alternative structures for the adsorption complexes, and then to look for molecular analogues of known structures whose spectra

Figure 9 The IR spectra of CO adsorbed on the silica-supported metals Cu, Pt, Ni, and Pd. Absorptions above 2000 cm^{-1} are from linear (on top) CO bonded to one metal atom; those below this value are from CO bridge-bonded to two or three metal atoms. Reprinted with permission from Eischens RP, Pliskin WA, and Francis S A (1954) *Journal of Chemical Physics* 22: 1786. Copyright 1954 American Institute of Physics.

can be obtained for comparative pattern-recognition purposes. This approach is well exemplified by the results obtained for chemisorption on metal surfaces, an area much studied because of the ready availability of single crystals of metals which can be cut so as to display particular surface planes.

Figure 9 shows high-coverage spectra obtained from CO chemisorbed on the silica-supported metals Cu, Pt, Ni, and Pd. The several metals show different proportions of absorption bands above and below 2000 cm^{-1} which are characteristic of adsorption on linear (on-top) and bridged sites, respectively. These structural assignments were deduced by comparison with the spectra of metal carbonyls. The spectral ranges attributable to such surface species are as follows: linear, $2120\text{--}2000\text{ cm}^{-1}$; twofold bridge, $2000\text{--}\sim 1870\text{ cm}^{-1}$; and threefold bridge $\sim 1900\text{--}1800\text{ cm}^{-1}$. These ranges apply whichever crystal face is involved. Within each range the characteristic absorptions increase in wavenumbers with increasing coverage. This is caused by strong vibrational coupling within the array of parallel

Figure 10 The IR spectra of CO adsorbed at full coverage on an Rh(111) electrode in 0.1 M NaClO_4 at various electrode potentials. Reprinted from Chang SC and Weaver MJ (1990) *Surface Science* 238: 142. Copyright (1990), with permission from Elsevier Science.

molecules on the surface, mostly of a dipolar nature related to the exceptional strength of the νCO absorptions. The mixture of linear and bridged CO species found from the spectra from the finely divided samples is caused by adsorption on different sites, usually different facets, on the metal particles.

Figure 10 shows νCO spectra at full coverage from chemisorption on an Rh(111) single-crystal electrode. These are plotted as a function of the electrode potential (with respect to a standard Ag/AgCl electrode) in 0.1 M NaClO₄ and show the interest of this additional variable in electrode work. It is seen that at the lowest electrode potential the spectrum is dominated by the absorption at 1886 cm^{-1} from a bridged species but at higher potentials, before desorption sets in, a linear species becomes dominant, absorbing at 2029 cm^{-1} . More generally, work on electrodes shows that, at a given coverage, negative potentials favour bridged species over linear species and that the wavenumbers of νCO absorptions from linear species increase in value with increasingly positive electrode potentials – a milder version of the dependence of νCO on metal oxidation state reported above.

Hydrocarbons on metal surfaces provide greater challenges in spectral interpretation and we choose the example of ethene chemisorbed on different metal surfaces. Here the relevant model compounds are inorganic binuclear or trinuclear metal clusters with the hydrocarbon ligand of interest and additional CO ligands occupying the positions of the metal atoms of the surface complex. One of the unexpected aspects of the adsorption of ethene is that (111) faces of many metals are covered by the dissociative ethylidyne species CH_3CM_3 ($\text{M} = \text{metal}$) near room temperature. Its spectrum was attributed to this structure by comparison with the spectrum of the model compound $(\text{CH}_3\text{C})\text{Co}_3(\text{CO})_9$, considered as a possibility because electron diffraction had shown that the CC bond of the adsorbed species is perpendicular to the surface. This example shows the importance of the metal–surface selection rule (MSSR). For this species, as a ligand or as a surface complex, the modes of vibration are fully separable into those with dipole changes either perpendicular or parallel to the surface (parallel or perpendicular to the CC bond, respectively). Only the former modes are active under the MSSR but both sets are active in the infrared spectrum of the model compound. **Figure 11** compares the infrared spectrum of the ethylidyne species on the Pt(111) surface with that of the model compound. The bands marked with asterisks in the spectra of the model compound (in order of decreasing wavenumber, νCH_3 symmetrical stretch, δCH_3 symmetrical bend and νCC stretch) are those which give dipole changes perpendicular to the surface; the other doubly degenerate modes give dipole changes parallel to the surface (νCH_3 asymmetric stretch, δCH_3 asymmetric bend and CH_3 rock). The positions of the ‘missing’ modes of the surface species,

Figure 11 A comparison of the IR spectrum from ethene adsorbed on Pt(111) at room temperature with that of the model compound $(\text{CH}_3\text{C})\text{Co}_3(\text{CO})_9$. Asterisks indicate absorptions of the model compound allowed in the spectrum of the adsorbed species by the metal-surface selection rule; arrows indicate other bands observed by HREELS. Figure 12 The structures of the principal adsorbed species from the adsorption of ethene on metal surfaces; [1] π -complex; [2] the di- σ species; [3] ethylidyne (CH_3C).

indicated by arrows, have been identified in the HREEL spectrum of the same system where the selection rules are more relaxed.

It has been shown by spectroscopy that at low temperatures ethene adsorbs on Pt(111) as the $\text{MCH}_2\text{CH}_2\text{M}$ (di- σ adsorbed) species with a cyclic C_2M_2 skeleton and that this transforms into ethylidyne on warming to near room temperature. The (111) faces of other metals, notably Pd and Cu, show low-temperature spectra from another less strongly perturbed H_2CCH_2 adsorbed species in which there is bonding from a single metal atom to the π -electron distribution of the $\text{C}=\text{C}$ double bond. Its spectrum is closer to that of ethene itself but with those modes which involve CC stretching occurring at lower wavenumbers. The structures of these three species are shown in **Figure 12**. **Figure 13** shows two spectra from ethene adsorbed on a silica-supported Pt sample, of the type used in catalysis, at 180 K and at room temperature. On these are indicated absorptions from the above three species with the MSSR-allowed modes still dominant. It is seen that the spectra from the catalyst sample are comprehensively accounted for in terms of

Figure 13 The IR spectra of ethene adsorbed on silica-supported Pt (a) at 180 K and (b) at room temperature, labelled according to the structural assignments of the absorption bands as given in **Figure 12**. Reprinted with permission from Mohsin SB, Trenary M, and Robota H *Journal of Physical Chemistry*, (1988) 92: 5229 and (1991) 95: 6657. Copyright 1988, 1991, American Chemical Society.

the species that had been identified one-at-a-time on single-crystal surfaces.

For the purpose of catalysis, the structure of the surface-adsorbed reactant should be sufficiently perturbed in order to promote reactivity, but not so strongly adsorbed that it cannot be removed by reaction. Below the temperature for the onset of catalysis, controlled by the energy of activation, the reactive species will be one or more of the chemisorbed species. The spectra of such species will weaken or disappear when catalysis commences while less reactive species are retained. In the case of ethene hydrogenation over metal catalysts, the order of reactivity in the presence of hydrogen is $[1] > [2] > [3]$, with [3], the ethylidyne species, being very slow to be removed. By room temperature over Pt/SiO₂, when the di- σ species has all been converted to ethylidyne, it is clear that the π -species, [1], is the catalytically active one. On Pt single crystals this mainly occurs on non-close-packed planes, and it may be inferred that catalytic reduction occurs on rougher, non-(111), surfaces of the metal particles. In a similar manner, it has been shown by single-crystal spectroscopy that the reactive species in the reduction of nitrogen to ammonia over the Fe catalyst (the Haber process) is a di- σ species involving the NN molecule chemisorbed to two Fe atoms which dissociates to adsorbed N atoms during catalysis.

The transition metal oxides form the other principal class of catalysts. These differ from the metals in that they have both acid and base sites in the same surface (the metal and oxygen atoms/ions, respectively) and react differently according to which of these properties is dominant. **Figure 14** shows the infrared spectrum from the heterolytic dissociation of hydrogen on polycrystalline ZnO to give surface HZn^+ and OH^- groups. Oxides

Figure 14 The IR spectra of hydrogen adsorbed on ZnO. Reproduced with permission of the Royal Society of Chemistry from Hussain G and Sheppard N (1990) *Journal of the Chemical Society, Faraday Transactions* 86: 1615.

have mostly been studied in the high-area form to date, including the zeolites whose acidic activity occurs on well-defined sites within the pores of the crystalline material. Flat single crystals of oxides are difficult to clean in UHV because of their insulating properties. 'Single-crystal' spectroscopic work on oxides is increasingly being carried out on thin films grown epitaxially on metal surfaces.

Other Vibrational Spectroscopic Techniques for Surfaces

Raman spectroscopy provides valuable complementary vibrational information to IR spectroscopy but its

applications to adsorbed molecules has been principally limited to the study of finely divided samples for reasons of reduced sensitivity. Exceptionally, flat monolayers of long-chain surfactant have given Raman spectra using multireflection techniques. Surface-enhanced Raman spectroscopy (SERS) gives greatly enhanced sensitivity but only for molecules adsorbed on the roughened surfaces of the coinage metals, particularly silver.

High-resolution electron energy loss spectroscopy (HREELS), with its higher sensitivity but lower resolution, has played a strongly complementary role to IR in the study of molecules adsorbed on single-crystal metal surfaces.

Inelastic neutron scattering (INS) and inelastic electron tunnelling spectroscopy (IETS) have found more limited applications to the study of the adsorption of molecules on high-area surfaces.

Surface-Enhanced Raman Scattering (SERS), Applications

Surface-enhanced Raman scattering (SERS) was first demonstrated by Fleischmann and colleagues in 1974. In a study of the adsorption of pyridine at a silver electrode, they noted that the Raman scattering was considerably stronger when the surface of the electrode was roughened. Jeanmaire, Van Duyne, Albreicht and Creighton reported that the Raman scattering from pyridine adsorbed on a roughened surface was enhanced by a factor of 10^6 compared to the equivalent concentration of pyridine in solution. This huge increase in signal stimulated a great interest in the technique and it remains one of its main advantages. The technique has been applied in many fields, including surface science, medicinal chemistry and analytical chemistry. Several books and reviews have been written: early developments were surveyed by Furtak and Rye, and Laserna has produced an informative overview indicating the potential to develop a powerful quantitative and qualitative analytical methodology. Chang and Furtak have written a comprehensive book on the subject. Articles directed towards specific applications include one by Vo Dinh targeted at chemical analysis and two by Nabiev and colleagues and Cotton and colleagues targeted at biological and medicinal applications.

The Mechanism of the Surface Enhancement

Two main mechanisms of the enhancement that produces SERS are now commonly proposed. These are electromagnetic enhancement and charge transfer or chemical enhancement. Electromagnetic enhancement does not require a chemical bond between the adsorbate and the metal surface. It arises from an interaction between surface plasmons on the metal surface and the adsorbed molecule. Chemical or charge transfer enhancement requires a specific bond between the adsorbate and the metal plus energy transfer between the metal and the adsorbate during the Raman scattering process. There is evidence for both mechanisms. The predominant view appears to be that both may occur.

Electromagnetic Enhancement

On smooth surfaces, surface plasmons exist as waves of electrons bound and confined to the metal surface.

However, on a roughened metal surface, the plasmons become localized and are no longer confined and the resulting electric field can radiate both in a parallel and in a perpendicular direction. When an incident photon falls on the roughened surface, excitation of the plasmon resonance of the metal may occur, causing the electric field to be increased both parallel and perpendicular to the surface. The adsorbate is bathed in this field and the Raman scattering is amplified. This mechanism has been studied and reviewed by Weitz, Moskovits and Creighton.

Since SERS has been obtained from molecules spaced off the surface, the existence of enhancement from this type of mechanism is well established.

Charge Transfer Enhancement

The enhancement from the charge transfer mechanism is believed to result from resonance Raman scattering from new resonant intermediate states created by the bonding of the adsorbate to the metal. The adsorbate molecular orbitals are broadened into resonance by interaction with electrons in the conduction band. Resonance states whose energies lie near the Fermi energy are partially filled, while those lying well below are completely filled. Otto has provided much evidence of the existence of this effect. He showed that there was a specific first layer and has extensively reviewed the field. Campion reported direct experimental evidence linking new features in the electronic spectrum of an adsorbate to SERS, under conditions where electromagnetic enhancements were unimportant. He noted that it was difficult to observe charge transfer only because the electromagnetic effects had to be accounted for and removed. This problem was overcome by conducting SERS on an atomically flat, smooth single-crystal surface where the electromagnetic effects were small and well understood. He adsorbed pyromellitic dianhydride (PMDA) on to copper(III) and observed an enhancement of a factor of 30. In addition, a low-energy band in the electronic spectrum from the adsorbed PMDA was observed that was absent in the solution PMDA spectrum.

Selection Rules

Selection rules have been derived for electromagnetic SERS enhancement. The advantage of electromagnetic

enhancement is that, since no new chemical species is formed on the surface, the selection rules can be based on the properties of the molecular adsorbate rather than on an ill-understood surface complex. In its simplest form, assuming no specific symmetry rules, the most intense bands are those where a polarization of the adsorbate electron cloud is induced perpendicular to the metal surface. However, more detailed selection rules can be obtained when the molecule has symmetry elements. Creighton and Moskovits have independently reviewed the principles.

Nature of the Substrate

The active substrates are usually made from a limited number of metals. Silver, gold and copper are the most commonly used SERS-active metals, although the use of lithium is well established. These substrates were chosen because their surface plasmons exist in or close to the visible region. Ideally, the excitation from the laser should coincide with the plasmon resonance frequency of the particular surface created and conditions such that the efficiency of absorption of the light is reduced and the efficiency of scattering increased. Silver is the most commonly used substrate, although gold is often used particularly in the near infrared. The original experiments used electrochemistry and this is a good method of obtaining a suitable surface. The scale of the roughness required is between about 40 and 250 nm for visible excitation with silver. SERS of pyridine obtained using an electrode setup results in certain bands appearing strongly in the pyridine spectra, and the relative intensity and absolute intensity are dependent on voltage. The maximum enhancement is believed to be when the Fermi level matches the energy of the π orbital of pyridine. The electrode working surface can be difficult to reproduce and is prone to annealing with time in certain environments. However, sensitive qualitative analysis is feasible.

Colloidal suspensions are particularly attractive as they can be prepared in a one-pot process and are inexpensive. Reliable SERS analysis is possible as a fresh surface is available for each analysis. Many different methods of colloid preparation have been reported. Some groups always use freshly prepared colloid for their experiments, but recent emphasis has been on obtaining reproducible, monodisperse colloid that is stable for several months. In particular, colloid prepared by the citrate reduction of silver can be produced in almost monodisperse form and with a lifetime of up to one year or more. The particle size of these colloids varies. In one standard preparation of citrate-reduced silver colloid, a transmission electron microscopy study indicated that the particles were approximately 36 nm in their longest dimension and were small hexagonal units (**Figure 1**).

Figure 1 Transmission electron microscopy image of silver colloid, $\times 250$.

Photoelectron correlation spectra of the suspension indicated that the average particle size approximated to a sphere of 28 nm.

Metal colloidal particles adsorbed upon or incorporated into porous membranes such as filter papers, gels, beads, polymers, etc. have been developed as SERS-active substrates. Although these substrates are claimed to be reproducible, they are not widely used, probably because they involve complicated preparative procedures and are susceptible to contamination and self-aggregation. Ruled gratings can be used to give good reproducibility and abraded surfaces, although not so reproducible, they are attractive because of their simplicity of preparation. Numerous researchers have reported that immobilization of the colloidal particles as ordered arrays on films gives reproducible and sensitive SERS sensors.

Surface-Enhanced Resonance Raman Scattering

Surface-enhanced resonance Raman scattering (SERRS) is obtained by using a molecule with a chromophore as the adsorbate and tuning the excitation radiation to the frequency of the chromophore. The effect was originally reported by Stacey and Van Dyne in 1983. The enhancement obtained is very much greater than that of either resonance Raman or SERS, enabling very sensitive analysis and low detection limits to be achieved. Although SERRS is best considered as a single process, it arose experimentally from the combination of two previously studied effects, namely resonance scattering and surface-enhanced Raman scattering (SERS). It is a unique process and different effects can be obtained depending on the nature of the chromophores used and the choice of laser excitation. **Figure 2** illustrates the

Figure 2 Illustration of the different arrangements for SERS: curve a is the molecular absorbance and curve b is the plasmon absorbance. In (a) the molecular and plasmon absorbances do not coincide. Position (1) represents excitation at the molecular maximum and (2) represents excitation at the plasmon maximum. In (b) the molecular and plasmon maxima coincide. Position (1) represents excitation away from molecular and plasmon maxima and (2) represents excitation at the absorbance and plasmon maximum.

main choices. In **Figure 2a**, the molecular chromophore (curve a) is chosen not to coincide with the maximum of the plasmon resonance (curve b). If laser excitation at the molecular absorption maximum is used, the maximum contribution to the overall effect from resonance enhancement would be expected. With the arrangement in **Figure 2a** and with the excitation at the molecular resonance maximum, it has been reported that for azo dyes there is reduced sensitivity to surface enhancement mechanisms, providing a signal that is less sensitive to the nature of the surface and that has a recognizable molecular 'fingerprint' related to the resonance spectrum, making this arrangement better for quantitative analysis.

The second possible arrangement illustrated in **Figure 2a** is where the laser excitation is set off the frequency of the adsorbate resonance and at the maximum of the plasmon resonance (2). For resonance experiments on the molecule alone, this would be described

as a preresonant condition and often SERRS undertaken in this way is written as SE(R)RS. More orientation information is to be expected and additional bands have been observed and assigned as due to mechanisms of surface enhancement. However, in this preresonant condition, the selectivity of resonance still applies. Thus, it is possible to pick out individual molecules in the presence of a matrix of interferents, but the effect will now be more dependent on the angle of the adsorbate to the surface. For many surface studies this is a key point and consequently this experimental process may be preferred for surface analysis.

Figure 2b gives an alternative case in which the molecular chromophore (curve a) coincides with the surface plasmon maximum (curve b). Similar considerations will apply, but a greater increase in sensitivity is likely at the resonance and plasmon resonance maximum frequency.

Hildebrandt and Stockburger carried out an extensive study on SERRS of Rhodamine 6G in order to explore the enhancement mechanisms involved. They reported that two different types of adsorption sites on the colloid surface were responsible for the enhancement experienced: an unspecific adsorption site that had high surface coverage on the colloid surface resulted in an enhancement factor of 3000 and could be explained by a classical electromagnetic mechanism; a specific adsorption site was only activated in the presence of certain anions (Cl^- , I^- , Br^- , F^- and SO_4^{2-}). This specific site had a low surface coverage (approximately 3 per colloidal particle); however, an enhancement of 10^6 was claimed to result. This enhancement was believed to be due to a charge transfer mechanism. This study was continued into the near-infrared region and extended to include gold colloid and gold and silver colloid supported on filter papers. The enhancement experienced from anion activation with silver colloid was stronger by a factor of 47 in the near-infrared region compared with the visible region. The authors concluded that this phenomenon could be accounted for by the charge transfer transition being shifted towards the red for Rhodamine 6G, increasing the resonance effect in the near-infrared region.

Advantages and Disadvantages of SERS/SERRS

SERS incorporates many of the advantages of Raman spectroscopy in that visible lasers can be used so that flexible sampling is possible, and there is little signal from water so that *in situ* examination of such surfaces as those of colloidal particles in aqueous suspension or of electrode surfaces under solvent can be carried out. The greatest advantages are the sensitivity that can be obtained and the selectivity of the signals. Since SERS will

detect compounds down to a level of about 10^{-9} M, adsorbates at monolayer coverage or less can be studied easily. Experiments on pyridine are a classic example. At well below monolayer coverage, pyridine is believed to lie with the plane of the ring almost flat on the metal surface. Under these conditions, there is very little intense Raman scattering since the main polarizability changes in the molecule are parallel to the surface. As the surface density of pyridine increases, the molecule is forced into a more vertical position and the signal begins to appear quite rapidly. This forms a good probe of when monolayer coverage occurs. Further, the existence of selection rules means that an indication of the nature of the surface processes can be obtained.

There are a number of key limitations to the method. First, to obtain a large effect, SERS can be used only for adsorbates on a limited number of metal surfaces in correctly prepared (roughened) form. Second, the very large surface enhancement coupled to the need for a specific molecule to be adsorbed on the surface makes the technique prone to interference. Contaminants that give strong surface enhancement can be detected in much lower concentration than the adsorbate studied, leading to problems in identification. The additional complexity that the intensity of the bands depends on only partially understood selection rules and can change depending on the angle of the molecule to the surface and the degree of packing makes it difficult to assign bands. Finally, there is a tendency in SERS for photodecomposition to occur on the surface. Characteristic broad signals that have been reported as being due to specific surface adsorbates are probably pyrolysed species on the surface. Notwithstanding these problems, SERS is unique in providing a fascinating insight into the adsorption mechanisms of molecules on suitable surfaces *in situ*.

The technique of SERRS might be assumed to have some of the same disadvantages as SERS and more limitations, but in fact SERRS is proving to be a much more effective technique for analytical science. The major advantage of SERRS is that, if correctly applied, the chromophore signal dominates. Since related spectra are obtained by resonance from solution, the spectra on the surface can easily be recognized, and since the Raman signal from the chromophore is enhanced more than any other molecule this particular species is very readily identified at the surface. Thus, in contrast to the difficulty in assigning signals in SERS in some cases, the signal assignment in SERRS is often simple and reliable. Further, and rather surprisingly, a fluorescence-quenching mechanism occurs on the surface so that both fluorescent and nonfluorescent dyes give good SERRS. Provided the molecule is attached to the surface, there is little fluorescence background. In fact, it is often useful to establish the fluorescence background against the strong SERRS signals in order to measure the degree of adsorption and

desorption from the surface. Thus, a wide range of chromophores is available. Further, the technique requires very low laser powers and consequently the photodegradation common in SERS is seldom a problem.

The characteristic spectra routinely observed with SERRS permit the identification of mixtures without the need for preseparation. Munro and colleagues have reported the analysis and characterization of 20 similar monoazo dyes, all of which produced unique characteristic spectra that in turn permitted the simultaneous analysis and detection of five dyes presented in a crude mixture. They addressed the problems associated with reproducibility and have focused much attention on improving and standardizing the production of the silver colloid generally used to obtain SERS. They concluded that, with careful attention to detail, a relative standard deviation (RSD) of 5% was routinely obtained.

Applications of SERRS and SERS

The advantages reported above have been exploited in numerous research fields, including the following.

Biochemistry SERRS methodology can be modified in order to provide a biocompatible environment for biological materials. The identification of water-soluble porphyrins and their photostability and interaction with roughened metal surfaces have been reported. For copper chlorophyllin, spectra obtained by using different excitation frequencies permitted a better understanding of a complex system. SERRS enabled the identification of novel chromophores in eye lenses without preseparation of the crude mixture. Finally the oxidation and spin state of proteins such as myoglobin and cytochrome P450 can be probed, and the use of a fluorescent low-concentration protein solution to study labelled tyrosines has been reported.

Medicinal chemistry SERRS has been used to detect the antitumour drug mitoxantrone and its interaction with DNA *in situ*. The adsorption of the drug complex onto a colloidal surface did not destroy or interfere with the native structure. Therefore, bonding information from the complex was extracted from the SERRS spectra. Selective detection of DNA at ultra-low levels by SERRS has been developed.

Surface chemistry SERRS has been used to probe electrode surfaces *in situ* to extract structural information and to provide quantification. The *in situ* SERRS detection of compounds such as 2,4,6-trinitrobenzene sulfonic acid covalently bound to tin oxide was observed when the chemically modified surface was coated with silver. The spectra collected provided rapid and sensitive

structural information that was semiquantitative. SERRS has also been used to follow reactions occurring at well below monolayer coverage at roughened metal surfaces.

Polymer science The ability to probe surfaces and boundaries using *in situ* SERS has been exploited extensively in polymer chemistry to characterize the surface of polymers for comparison with the bulk properties, and to determine the molecular geometry, orientation of polymer side groups adjacent to the metal surface and information on bonding, for example of polymer-metal composites such as adhesives and coatings.

Forensic science Modern Raman spectrometers connected to microscopes enable the examination of small amounts of material such as single fibres. The sensitivity and selectivity of SERRS can be exploited in forensic science by determining the nature of the dye mixture *in situ* from a single fibre, from an ink or from a lipstick smear.

Corrosion science Studies of corrosion inhibitors, particularly for copper using SERS of the inhibitor adsorbed on the roughened metal surface, have been used to selectively identify the species. The limitation of requiring a roughened metal surface of a particular metal can be overcome by applying colloid to a smooth nonactive surface.

Practical uses of SERRS have been developed. It has been used to prepare a robust disulfide pH indicator by coupling pH-sensitive dyes – methyl red, cresol violet and 4-pyridinethiol – to cystamine, which adsorbs strongly to the roughened metal surface, forming monolayer coverage of the complex with colloidal silver and allowing strong SERRS to be recorded. Changes in the pH result in changes in the chromophores of the dyes that were easily detected by SERRS. As the SERRS spectrum obtained from the complex was pH sensitive, it was possible to obtain quantitative pH determination.

Another example involves the exploitation of the sensitivity of the technique to analysis of trace amounts of nitrite in fresh and sea waters: sulfanilamide was added to the water sample and reacted with any nitrite present, forming a diazonium salt that was then coupled with ethylenediamine to produce an azo dye that was then detected by SERRS. An enhancement of a factor of 10^9 , a relative standard deviation of 10–15% and a limit of detection of picograms were reported. This method was superior to existing colorimetric and chemiluminescence techniques used to analyse the water samples for nitrite. Ultrasensitive detection of metal ions has been reported. A limit of detection at the nanogram level was claimed. The metal ions nickel or cobalt and a ligand, a mixture of 2-pyridinecarboxyaldehyde and 2-pyridinehydrazone or

1,10-phenolanthroline, form a complex on the roughened metal surface that is then detected by SERRS.

Single Molecule Detection

Rhodamine 6G has been used extensively as a model dye to probe the nature of the SERRS effect. It is an extremely strong fluorophore when excited by visible radiation. Hence normal Raman is not observed except with near-infrared excitation. However, when SERRS is used the dye adsorbs strongly to the roughened metal surface and consequently this strong fluorescence is quenched and an extremely strong, enhanced Raman signal is observed. **Figure 3** illustrates the resonance Raman and SERRS spectra collected from Rhodamine 6G. Attomolar levels (10^{-18} M) of detection have been reported for this system, which is approaching single molecule detection. The fluorescence-quenching properties of surface enhancement coupled with the additional sensitivity obtained from SERRS have been exploited by several researchers. Rhodamine 6G adsorbs very effectively on the roughened silver surface. However, the detection of single adsorbates of dopamine or phthalazine on colloidal clusters, with a limit of detection

Figure 3 Curve a: Solution spectrum from a 10^{-6} M Rhodamine 6G solution using 514.5 nm excitation, demonstrating the predominance of fluorescence over resonance Raman scattering. Curve b: SERRS spectrum taken from a suspension of aggregated silver colloid to which 150 μ L of a 10^{-8} M Rhodamine 6G solution has been added using 514.5 nm excitation.

at picogram levels, illustrates that ultrasensitivity of this technique for other adsorbates is possible.

The ability of SERRS to detect one molecule has been demonstrated by three groups. Nie has isolated colloidal particles with rhodamine adsorbed onto glass slides and obtained spectra from the individual particles. The particles are preselected for size to ensure that the surface plasmon of the single particle is in the visible region. Kneipp has used near-infrared anti-Stokes scattering and statistical methods to demonstrate that single molecules can be observed in suspension and Graham and colleagues have shown that one molecule of DNA labelled with a covalently attached fluorescein dye can be detected in the interrogation volume of suspended and aggregated colloid.

Conclusion

In summary, surface enhancement results in a huge enhancement in Raman scattering and the ability to observe Raman signals at very low concentrations. The resulting spectra provide molecular information and are unique to individual molecules. Sample preparation is simple and it is possible to undertake analysis *in situ* under water or in air or in vacuum. Since there are new selection rules and the effect is dependent on the metal used and the degree of surface roughness, there is a wealth of surface information to be obtained from SERS provided the limitations in terms of contamination and photodecomposition are remembered. The main problems are the limited number of surfaces to which the method can be applied and difficulties in interpreting the spectra.

Additional advantages can be obtained from the use of SERRS. It is more sensitive and the resulting spectrum can be related back to the molecular resonance spectrum,

making for more confidence in assignments. Fluorescence is quenched, signals from the adsorbate are much more intense than from contaminants and there is less dependence on the exact nature of the surface. This makes for unique applications for SERRS, which include simpler, more sensitive and more selective quantitative analysis and single molecule detection.

This article is reproduced from the previous edition, volume 3, pp 2335–2339, © 1999, Elsevier Ltd.

In this brief article an attempt is made to review those aspects of group theory that may be of concern to a non-specialist reader. It is written on the assumption that the reader may at some point decide to study a particular aspect of the subject in more detail. However, specialist articles are not always the most accessible and so a particular effort has been made to explain key points in non-mathematical terms. Hopefully, this will provide an insight which will be helpful should the going get tough! For simplicity, reference will always be made to 'molecules'. This should in no case be taken to exclude other species.

Modern spectroscopy makes extensive use of group theory. It does so at several related points. Perhaps most important is in the interpretation of the data that it produces. However, spectral interpretation does not stand alone. In order that the data may be interpreted, the states to which they relate must also be subject to a group theoretical description. In that the states are normally product functions of some sort, the individual functions must themselves have a group theoretical basis. Then, the spectral data correspond to transitions that are made allowed by virtue of some physical process – electric dipole transitions are perhaps the most widely studied but the continuing growth of NMR and EPR methodologies, *inter alia*, is making magnetic dipole transitions of increasing importance; it is also relevant when optical activity is the subject of discussion. The physical process also has to be susceptible to a group theoretical description.

There is an alternative approach to the topic which is of no less validity. This is the study of commuting operators. The statement that two operators commute is equivalent to the statement that you can, in principle at least, make simultaneous measurements of the physical properties associated with each of them. The set of operators that make up the point group of a molecule commute with the Hamiltonian operator and so one can have knowledge of energies which correspond to symmetry-distinct levels. If one can recognize the existence of a valid operator then it can be used in the classification of energy levels; there is no requirement that one can implement in some way the associated physical process. The permutation operator and time-reversal operators fall into this category, but so too do the operations of the point groups of spectroscopic importance. So, it can prove convenient to extend the concept of the group of

operations which commute with the Hamiltonian beyond the simple point group operators and to incorporate others with them.

But, to begin at the beginning. To the majority of users the applications of group theory to spectroscopy start with the simple point groups. The symmetry of a molecule is expressed by the statement that there exist within it certain symmetry elements, such as rotation axes or mirror planes, which relate equivalent parts of a molecule to each other. To apply such an approach there is an implicit assumption that the molecule is a rigid body locked into its lowest potential energy arrangement. It is commonplace to state that it is not the symmetry elements that are of importance but, rather, the corresponding operations. More accurate still is to state that it is the corresponding operators that are of importance, since it is they which commute with the Hamiltonian. It is also important to recognize that there is no requirement of a 1:1 relationship between symmetry element and operator. There is only a single identity (leave alone) operator – often denoted E – but for any molecule there is an infinite number of C_1 axes (C_n means rotation by $360/n$). There is a 1:2 relationship between C_n , $n > 2$, axes and the corresponding C_n operators. Other symmetry elements/operators that will commonly be encountered are mirror planes/mirror plane reflections, denoted σ . These admit of a classification into three types. First, σ_v , where the v stands for vertical and indicates that the mirror plane contains the rotational axis of highest n (i.e. if the axis is vertical, so too is the mirror). Second, σ_h , where the h stands for horizontal and indicates that the mirror plane is perpendicular to the rotational axis of highest n (i.e. if the axis is vertical, the mirror is horizontal). Third, σ_d , where the d is the first letter of the word diagonal. These mirror planes bisect the angle between two twofold axes and also have an axis of at least twofold symmetry lying in them. Care is needed, however, because the use of the symbol σ_d is subject to abuse. If a set of mirror planes is correctly labelled σ_d in one point group, they may well be labelled the same way in a subgroup, even though the latter does not contain the twofold axes of the parent. Other symmetry elements/operators are a centre of symmetry/inversion. These are commonly denoted i (the same symbols are usually used for symmetry element and operator, although different fonts may be used to distinguish them). The final

symmetry elements/operators are denoted S_n . They correspond to a rotation about $360/n$ followed either by reflection in a plane perpendicular to the axis or by inversion in the centre of mass of the molecule. Either definition may be used; the sets resulting are in a 1:1 correspondence. The former definition is perhaps the more popular but the latter is perhaps the more useful (it is convenient to have a simple way of determining parity in a descent in symmetry from spherical to point group). Each set of symmetry operators comprises a group which is given a unique label, usually a combination in some way of the labels used for the operations that it contains. An exception to this is found for those groups which have a symmetry such that the coordinate axes are all symmetry related. They have individual names (I_h , O_h , T_d are the labels of the most important icosahedral, octahedral and tetrahedral groups).

The combination of the group operators gives rise to a group multiplication table and the characters of sets of matrices which multiply isomorphically to the group operators are collected in character tables. These character tables are the starting point for many applications and are widely available, most commonly as appendices in relevant books. A typical character table is given in **Table 1**.

The table of characters is square; each row corresponds to a different irreducible representation of the group. Each irreducible representation has a unique label, given at the left-hand side, such labels are widely used. The label E (with or without suffixes or primes) indicates double degeneracy. Not used here, but the label T (or sometimes F) indicates triple degeneracy. For emphasis, the characters are divided into four sets which will be seen to have a very simple relationship with each other. At the right-hand side of the table are given two columns of basis functions. These are functions which may be used to generate the set of characters in their row but, more usefully, they provide information which can be useful in a spectroscopic analysis. For instance, the electric dipole operators have the same symmetry species as the coordinate axes (here, $A_2'' + E'$). One important use of character tables is to decompose reducible representations into their irreducible components. Reducible

representations are produced by most real-life applications of group theory to molecular problems, when a sum of irreducible representations is generated and the details of the sum have to be determined. For instance, immediately beneath the character table is a reducible representation which has $2A_2' + E' + E''$ components. There are simple systematic ways of decomposing reducible representations based on the orthonormality of the irreducible representations. This can be seen in that the product of pairs of characters of any two different irreducible representations, summed over every operation of the group, sums to zero. On the other hand, the squares of characters of any irreducible representation, summed over all of the operations of the group, sum to the number of operations in the group, 12 in the group above.

One cannot go far in spectroscopy without encountering product functions. The individual component functions of product functions have their symmetry properties described by one of the irreducible representations in the appropriate character table. In order to determine the symmetry species of the product function a table of direct products is needed, which enables this to be determined from the irreducible representations of the component functions. Such direct product tables may be obtained from the corresponding character table. That corresponding to the D_{3h} group is shown as **Table 2**.

The symmetry of **Table 2** arises, of course, because it results from the multiplication of numbers. Such direct product tables can be used to determine the symmetry species of product functions, irrespective of the number of functions; they can be included in sequence. So, the symmetry of the first overtone or combination bands in vibrational spectroscopy is immediately obtained from a direct product table. However, care has to be taken in the case of overtones of degenerate vibrations. The case of the first overtone illustrates the problem. For the overtone of a doubly degenerate mode there are just three overtone functions, roughly aa, ab and bb. Four are given in the table above. Similarly, for the overtone of a triply degenerate mode the overtone functions, roughly, are aa, ab, bb, bc, cc and ca, six in total, compared with the nine that appear in a direct product table. The reason is that the direct product can be divided into a symmetric and an antisymmetric part (with respect to interchange of the

component functions). For overtones, only the symmetric part is relevant, the antisymmetric functions self-cancel (the functions above are rough because they are not all properly symmetric).

Direct product tables also have importance in determining the selection rules of spectroscopy. The statement that a particular transition is allowed is a statement that a transition moment integral is nonzero. Selection rules are general statements about which of all of the possible transition moment integrals can be nonzero. It is group theory which is used to determine which integrals can be nonzero.

An integral may be regarded as the sum of an infinite number of tiny component contributions, one from each of the infinite number of tiny volume elements of space. But for any given tiny volume of space there are $(n-1)$ symmetry-related tiny volume elements (where the number of symmetry operations in the group is n ; n is often called the 'order' of the group). When all of the symmetry-related volume elements make equal (in magnitude and sign) contributions to the integral their sum does not vanish and the integral (which includes the contributions from all of such sets) is nonzero. If $n/2$ of the symmetry-related tiny volume elements are positive and $n/2$ are negative then their combined contribution to the integral is zero. Since this pattern is repeated for each and every set of symmetry-related tiny volume elements, the integral itself is zero. But can one make statements about the phase relationships between the symmetry-related members of sets of tiny volume elements?

Character tables such as **Table 1** are statements about the phase relationships between functions in the space spanned by the character table. For instance, it is easy to see that any A'_2 function has equal positive and negative contributions – multiply each A'_2 character by the number of regions of space to which it refers (the numbers at the head of each column) – and so an integral over all space is symmetry-required to be zero. Only integrals of A'_1 symmetry (in the D_{3h} point group) can be nonzero. In general, only integrals which transform as the totally symmetric irreducible representation (which always has characters of $+1$) of a group can be nonzero. Now, this irreducible representation always occurs on the leading diagonal of the table of direct products and nowhere else in this table. This means that it occurs whenever the direct product is one formed between an irreducible representation and itself. It is this matching which is the basis of simple selection rules. For instance, the often-stated requirement for infrared activity – that to be spectrally active a vibrational mode has to transform like a coordinate axis. This arises because in the triple direct product derived from the symmetry species of:

(excited state) (operator) (ground state)

the vibrational ground state is totally symmetric – the molecule is assumed to be nonvibrating (actually, it would almost be equally valid to say that it is assumed that only nondegenerate vibrations are excited in the ground state – this is the way the group theory works out). For the corresponding integral to be nonzero, the symmetry species of the excited state (which is the symmetry of the mode excited) has to be the same as that of the operator. It is an electric dipole transition and so the symmetry of the operator is that of an electric dipole – and this is the same as that of a coordinate axis.

All of this has assumed a rigid, isolated, molecular species. If we are interested in molecular rotations, the theory clearly needs extension – it covers bulk rotations (these find a place in the list of basis functions in the character table above) but there is nothing evident in the theory which would enable the classification of rotational energy levels. Equally, the zero point vibrational energy – and its destructive effect on the assumed molecular geometry – has conveniently been neglected. In fact, there is a validity in this last step. It arises from the fact that the vibrations of a molecule are such that it explores a multidimensional space (each molecular vibration represents an independent variable and so the greater the number of vibrations, the greater the number of dimensions that the molecule can explore vibrationally). This multidimensional space has an inherent symmetry. Thus, if a molecule has (when rigid) a mirror plane of symmetry, then if it is distorted there will be another configuration which is of equal energy to the first but the mirror image of it. That is, all of the symmetry operations of the rigid molecule have a relevance to the multidimensional potential surface. In fact, if one works through the theory, one ends up with a group which is isomorphic to that of the rigid molecule. It is for this reason that the use of the rigid-molecule group gives valid results – it is isomorphic to the correct group. This theory might be called the theory of nearly rigid molecules; molecules that make but small deviations away from an equilibrium geometry. What of the other extreme – molecules which, whilst retaining their molecular identity, are nonetheless internally very mobile. One has to deal with the molecular symmetry group (as opposed to the molecular point group) of a molecule. Consider what has become a classic example, the molecule CH_3BF_2 , which has a rather free rotation about the C–B bond axis. Consider the molecule in a configuration in which it has no point group symmetry other than the identity. Appropriate is an arrangement in which, viewed down the C–B axis, one F almost eclipses an H. Suppose that the H is slightly to the left. Two arrangements of equal potential energy can be generated by rotating one of the two other hydrogens into the position occupied by the first. Three equienergetic arrangements in all. Three more can be obtained by rotating the second F to take the place of the first. Now we

have six equivalent arrangements. Six more can be obtained if we go back to the beginning but now place the H in an equivalent position but now to the right. The (physically feasible) interconversions which relate these 12 arrangements constitute the molecular symmetry groups of CH_3BF_2 . The definition of 'physical feasibility' is at the heart of the definition of the molecular symmetry group of a molecule and, in contrast to the definition of a molecular point group, has sometimes proved somewhat controversial. In part, at least, this has resulted from attempts to define such groups in a compact way. For instance, inversion of the positions of all particles in the centre of mass of the molecule – a physically highly unfeasible operation – can usefully be included!

Next, the assumption of an isolated molecule. When in solution, a molecule will be subject to an infinity of different solvent environments, unless there is some reason that a particular solvent is 'frozen' around the dissolved species. Such cases are rare. The infinity of environments will cause a broadening of most spectral transitions but there is little more that can be said in general. Much more can be said when the environment is that of a crystalline solid. For a solid, formally, one is not concerned with a point group but, rather, with a space group. These are the space groups of classical crystallography but care has to be taken in that classical crystallography may make use of a nonprimitive unit cell (body or face centred). For spectroscopic purposes it is essential that only primitive unit cells are used (a unit cell, by pure translations, generates the entire crystal. If one doubles the size of the unit cell, by body-centring it, for instance, then the number of translation operations is halved). Even so, it is to be noted that there is no unique definition of a unit cell. If the spectroscopy is such that the surface of the crystal is not of importance then the crystal faces are ignored and the crystal is, effectively, infinite. An important simplification arises because for the vast majority of spectroscopic measurements performed on a crystal, the wavelength of the incident radiation is much greater than a typical primitive lattice translation vector. This enables the use of a so-called factor group in which the entire set of translation operations are incorporated into the identity operation. The set of operations which remain are isomorphic to one of the 32 crystallographic point groups; this isomorphism is exploited by the use of the character table of the appropriate one of the 32 crystallographic point groups in the subsequent analysis. Pictorially, one can think of there being a coupling between all of the molecules within a (primitive and, of course, arbitrary) unit cell, but in reality the formal analysis covers all unit cells. The method of analysis can be called the 'unit cell' or 'factor group' models (they differ in approach, not results); the splittings that occur on 'molecular' features are referred to as 'factor group', 'correlation field' or 'Davydov'

splittings. If coupling between molecules does not have to be invoked, the molecular environment in the crystal, the site, may well lead to splittings in (molecular) degenerate modes – site symmetries are commonly lower than molecular. The 'site group' model is then appropriate and the splittings are known as 'site splittings'. The irreducible representation of the group of all translations does not enter any of these analyses. However, they become important in vibrational spectroscopy, for example, if anharmonic vibrations are considered (and they well may be, involving for instance, coupling with lattice modes). In such cases the Brillouin zone, representing the k vectors which define the irreducible representations of the group of all translations, has to be invoked.

Related to the spectroscopy of crystals is the spectroscopy of surfaces and, particularly, the spectroscopy of species adsorbed on crystal surfaces. For perfectly conducting metals, there is an important selection rule in that such surfaces image any electric dipole within an adsorbed molecule. When such dipoles are perpendicular to the surface the dipoles reinforce; when they are parallel to the surface they cancel. This gives rise to the so-called 'surface selection rule', that it is only possible to observe by electric dipole spectroscopy those modes which involve dipole moment changes perpendicular to the surface. This requirement can be expressed group theoretically by use of the so-called diproduct groups in two dimensions.

Often not too far away from an application of group theory in spectroscopy is the fact that functions derived from atomic orbitals are under study. The study of the group theory of spherical symmetry is fascinating, an infinitesimal rotation about any axis being a symmetry operation. The corresponding infinitesimal rotation operators have important commutation relationships which provide a basis for the theory of angular momentum, for instance. The descent from spherical to molecular symmetry usually means a reduction in degeneracy. For a species corresponding to an angular momentum j the character, χ , corresponding to a rotation of θ° is given by:

$$\chi_j(\theta) = \frac{\sin \frac{1}{2}(2j+1)\theta}{\sin \frac{1}{2}\theta}$$

This equation is equally applicable when j is half-integral but then it is necessary to work in the so-called double group, in which the factor of $\frac{1}{2}$ in front of the θ means that a rotation of 720° is required to give the identity. Corresponding to each operation in the $0-360^\circ$ sector there is another in the $360-720^\circ$. A C_2 rotation still corresponds to a 180° rotation but it now takes four such operations in succession to generate the identity. Perhaps not surprisingly, C_2 in a double group closely resembles C_4 in a 'normal' group. So, although the group C_{2v} is Abelian (all characters $|1|$), the C_{2v} double group has

degenerate representations – and, indeed, its character table is isomorphic with that of the C_{4v} ‘normal’ group.

An important application of group theory in spectroscopy arises from the recognition that direct products are at the heart of the topic. Consider the case where two degenerate irreducible representations combine to give a reducible representation (which they invariably do). Of course, the irreducible representations could describe either operators or functions. The irreducible components of the reducible representation will be linear combinations of functions of the type that we have already met, aa , ab , ac , bc , etc. (these functions have the disadvantage that they occur in a direct product of an irreducible representation with itself; however, we seek to illustrate the principle, not to give a general example). The coefficients which relate the basis functions of the starting irreducible representations to the final combinations of product functions do not depend on the particular problem in hand. The so-called vector coupling or ‘Clebsch–Gordon’ coefficients are universal and so tables of them are available. However, care is needed in their use. This is because for any degenerate irreducible representation an infinite number of choices of basis function is of equal validity and can be used. But the coefficients just introduced are based on a specific choice of basis functions; these same functions must be used in the application of tables of coupling coefficients or errors will surely result (and sometimes the basis functions chosen are not the most obvious – the reason why will become evident in the next paragraph). There are several important outcomes from the use of coupling coefficients. The existence of coupling coefficients means that the final functions are related. If one final (product) function, which could be the intensity of a spectral transition, were available, either by calculation or by measurement, then the values of all of the others follow, based on a so-called ‘reduced matrix element’ (which is written mathematically with two bars on each side of the operator). This is

the Wigner–Eckart theorem. Related to this is the so-called replacement theorem. If the relative values of a set of integrals are determined using coupling coefficients then the same pattern holds for a different set of integrals involving basis functions from the same irreducible representations. The two sets of integrals are proportional to each other. This can be very useful if, for example, one only has an approximate expression for an operator or wavefunction.

It is evident that the more the symmetry, the greater the utility of coupling coefficients. Put another way, the greater the inherent degeneracies, the greater their use. The logical consequence of this is that they will be of greatest use in spherical symmetry (and the descent from spherical symmetry to point group symmetry has been described above). In spherical symmetry, that which we have called vector coupling coefficients become replaced by $3j$ symbols (j as in j – j coupling) and higher extensions, the $6j$ and $9j$ symbols. These nj symbols have many advantages. First, they are defined in such a way that they are basis-independent. Second, they summarize in compact form what would otherwise be lengthy summations. Those practised in the art use them wherever they can!

Introduction

Tensor representations, synonymous for product representations and their decomposition into irreducible constituents, are useful concepts for the treatment of several problems in spectroscopy. Important examples are the classification of the electronic states in atoms and the derivation of selection rules for infrared absorption or the vibrational Raman or hyper-Raman effect in crystals. In the first case the goal is to reduce tensors which are defined as products of one-particle wave functions, while in the second case tensors for the dipole moment, the electric susceptibility or the susceptibilities of higher orders have to be reduced according to the irreducible representations of the relevant point groups.

Basics of Group Theory

Group Postulates

A set of elements $g_1, g_2, \dots$ forms a group $\mathbf{G}$ if there is a composition law defined for the elements such that the following conditions are satisfied:

$$g_i g_j = g_k, \quad g_k \in \mathbf{G} \quad [1]$$

$$(g_i g_j) g_k = g_i (g_j g_k) \quad [2]$$

$$g_i e = e g_i = g_i \quad [3]$$

$$g_i g_i^{-1} = g_i^{-1} g_i = e \quad [4]$$

Equation [1] represents the binary composition law, eqn [2] states the associative law, eqn [3] shows the existence of an identity element, and eqn [4] shows that to each $g \in \mathbf{G}$ there exists a unique inverse element.

Conjugate Elements and Classes

For any given group element $g_i \in \mathbf{G}$ the product $g g_i g^{-1}$ can be formed for any arbitrary $g \in \mathbf{G}$ and is called the

conjugate element of g_i by g . This defines an equivalence relation which subdivides the group $\mathbf{G}$ into mutually disjoint subsets where the latter, symbolized by $[g_i] = \{g g_i g^{-1} | g \in \mathbf{G}\}$, are called classes of conjugate elements.

Products of Groups

Direct product of groups

Consider two groups $\mathbf{L}$ and $\mathbf{M}$ and let $\mathbf{L} \times \mathbf{M}$ be the product set which consists of all ordered pairs $\{(l_j, m_k) | l_j \in \mathbf{L}, m_k \in \mathbf{M}\}$. The set $\mathbf{L} \times \mathbf{M}$ defines a *direct product* group, if its composition law is defined by:

$$(l_j, m_k) * (l_r, m_s) = (l_j l_r, m_k m_s) \quad [5]$$

If $\mathbf{L}$ and $\mathbf{M}$ are finite groups, then the order $|\mathbf{L} \times \mathbf{M}|$ of the product group is given by $|\mathbf{L} \times \mathbf{M}| = |\mathbf{L}| \cdot |\mathbf{M}|$, where the symbol $|\mathbf{G}|$ denotes the order of some group $\mathbf{G}$.

Kronecker product of groups

The special case $\mathbf{L} = \mathbf{M} = \mathbf{G}$ allows one to define the product group $\mathbf{G} \times \mathbf{G}$ which contains as a special subgroup $\mathbf{G} \boxtimes \mathbf{G} = \{(g, g) | g \in \mathbf{G}\}$ that is isomorphic to the group $\mathbf{G}$. The subgroup $\mathbf{G} \boxtimes \mathbf{G}$ is sometimes called the *Kronecker product* group or likewise *diagonal subgroup* of the direct product group $\mathbf{G} \times \mathbf{G}$.

Representations of Groups

Matrix representations

If for every element $g_i \in \mathbf{G}$ there is a corresponding element $g'_i \in \mathbf{G}'$, such that if $g_i g_j = g_k$ in $\mathbf{G}$, it follows for the corresponding product of operations $g'_i g'_j = g'_k$ in $\mathbf{G}'$, then the two groups are said to be *homomorphic*. A *representation* of a group is defined as a group of nonsingular square matrices homomorphic with the group. The number of rows (columns) of the matrices is called the

dimension of the representation. Consider the product $g_i g_j = g_k$ in $\mathbf{G}$. The analogous product of representation matrices is written as:

$$G(g_i)G(g_j) = G(g_k) \quad [6]$$

Carrier spaces – linear operator representations

A vector space V is called the carrier (or representation) space for the group $\mathbf{G}$ if there exists a homomorphic image of $\mathbf{G}$ of operators $O(\mathbf{G}) = \{O(g) \mid g \in \mathbf{G}\}$ that leave the space V invariant. The representation $O(\mathbf{G})$ is called the *linear* operator representation $L(\mathbf{G})$ of $\mathbf{G}$ in V if the operators $O(g) = L(g)$ are linear ones. If V is a unitary space and each operator $L(g) = U(g)$ leaves any scalar product invariant, then $U(\mathbf{G})$ is called a *unitary* operator representation of $\mathbf{G}$ in V .

For instance, the Hilbert space $L^2(\mathbb{R}^3)$ is the carrier space for the 3-dimensional rotation group $\mathbf{O}(3, \mathbb{R}) = \mathbf{SO}(3, \mathbb{R}) \times \mathbf{C}_i$ where $\mathbf{C}_i = \{e, i\}$ and the symbol i denotes the inversion operation ($\vec{x} \rightarrow -\vec{x}$) in $\mathbb{R}^3$, respectively. If, using the *Euler* angles to characterize the group elements $g = (\omega) = (\alpha, \beta, \gamma) \in \mathbf{SO}(3, \mathbb{R})$ then the linear operators

$$U(\omega) = \exp(-i\alpha L_z) \exp(-i\beta L_y) \exp(-i\gamma L_z) \quad [7]$$

$$[U(i)f](\vec{x}) = f(-\vec{x}) \quad [8]$$

define a unitary operator representation of $\mathbf{O}(3, \mathbb{R})$ on $L^2(\mathbb{R}^3)$, where $f \in L^2(\mathbb{R}^3)$ represents an arbitrary function of the Hilbert space in question and where the operators L_x, L_y, L_z denote the Cartesian components of the orbital angular momentum operator.

As another example, the Hilbert space $L^2(\mathbb{R}^3) \otimes \mathbb{C}^2$ is the carrier space for the direct product group $\mathbf{O}(3, \mathbb{R}) \times \mathbf{SU}(2)$ where the unitary operators $U(\omega, i^\sigma) = U(\omega)U(i^\sigma)$ with $\sigma = 0, 1$ that are defined by eqns [7] and [8] represent the orbital part together with the spin part a unitary operator representation of $\mathbf{O}(3, \mathbb{R}) \times \mathbf{SU}(2)$ on the Hilbert space in question. The spin part reads:

$$V(\omega') = \exp(-i\alpha' S_z) \exp(-i\beta' S_y) \exp(-i\gamma' S_z) \quad [9]$$

where the entries S_x, S_y, S_z denote the Cartesian components of the intrinsic (spin) angular momentum which are proportional to the *Pauli* matrices σ_j respectively. Here, it should be noted that due to the fact that $\mathbf{SU}(2)$ represents the universal covering group of $\mathbf{SO}(3, \mathbb{R})$, the range of variation of the group parameters $(\omega') \in [0, 2\pi) \times [0, \pi) \times [0, 4\pi)$ describing $\mathbf{SU}(2)$ -elements differs from that of $(\omega) \in [0, 2\pi) \times [0, \pi) \times [0, 2\pi)$ describing $\mathbf{SO}(3, \mathbb{R})$ elements. In fact, $\text{Ker}_\varphi = \{(0,0,0), (0,0,2\pi)\}$ where $\varphi(\mathbf{SU}(2)) = \mathbf{SO}(3, \mathbb{R})$ represents the nontrivial kernel of the homomorphism. Apart from this, we have

$$W(\omega, i^\sigma, \omega') = U(\omega, i^\sigma) \otimes V(\omega') \quad [10]$$

where $W(\omega, i^\sigma, \omega')$ denotes an arbitrary element of the unitary operator representation $U(\mathbf{O}(3, \mathbb{R}) \times \mathbf{SU}(2))$ acting on the Hilbert space $L^2(\mathbb{R}^3) \otimes \mathbb{C}^2$. In this context it should be noted that $L^2(\mathbb{R}^3)$ is used to describe the quantum mechanical motion of a spinless particle in 3 dimensions, whereas $L^2(\mathbb{R}^3) \otimes \mathbb{C}^2$ is used as the carrier space to describe the quantum mechanical motion of a particle with spin $\frac{1}{2}$ in 3 dimensions.

Basis of a representation

Let $\mathcal{H}$ be the carrier space of the group $\mathbf{G}$ whose elements $g \in \mathbf{G}$ are represented by unitary operators $U(g) \in U(\mathbf{G})$, which is typical when applying group theoretical methods to quantum mechanical problems. Assume that $\dim \mathcal{H} = n$ and consider a set of n linearly independent functions φ_i defined in this configuration space with the property:

$$U(g)\varphi_k = \sum_{i=1}^n G(g)_{ik}\varphi_i \quad [11]$$

This set of functions defines a basis for the representation G . It is clear from the last equation that the representation matrix for some particular group operation is completely defined if a basis is given and vice versa. It is therefore convenient to label the representation according to the basis, e.g. $G_\varphi(g)$ in order to stress the basis dependence of multidimensional matrix representations. Note in particular, if $\{\varphi_j \mid j=1, 2, 3, \dots, n\}$ defines an orthonormal basis, then the corresponding matrix representation $G_\varphi(\mathbf{G}) = \{G_\varphi(g) \mid g \in \mathbf{G}\}$ of $\mathbf{G}$ must be a unitary one.

Reducibility of representations, irreducible representations

Multidimensional matrix representations of groups are not unique and, if defined via bases of some carrier spaces, sensitively depend on the chosen basis. Any nonsingular linear transformation of the basis $\{\varphi_j \mid j=1, 2, 3, \dots, n\}$ to a new basis say $\{\psi_j \mid j=1, 2, 3, \dots, n\}$, leads to the following well-known transformation formulae:

$$\psi_k = \sum_{i=1}^n C_{ik} \varphi_i \quad [12]$$

$$G_\psi(g) = C^{-1} G_\varphi(g) C \quad [13]$$

where C is an invertible matrix with coefficients C_{ij} defining a similarity transformation. Note in passing, if $\{\varphi_j\}$ and its counterpart $\{\psi_j\}$ are orthonormal bases of the $\mathbf{G}$ -invariant carrier space $\mathcal{H}$, then C can be chosen unitary without any loss of generality and the matrix representations $G_\varphi(\mathbf{G})$ and $G_\psi(\mathbf{G})$ are unitary too.

A representation is *reducible* if there is a matrix C which converts all matrices of a representation into the

same block-diagonal form. When such a matrix is found the reducible representation is decomposed into a number of representations of dimensions smaller than the original dimension. Representations found in the reduction process that cannot be reduced further are called *irreducible representations*. There are a number of theorems for irreducible representations valid in particular for *finite* groups which shall be given without proof:

1. The number of irreducible representations which are nonequivalent, i.e. not related by a similarity transformation, is equal to the number of classes in the group.
2. The sum over the squares of the dimensions of the irreducible representations is equal to the number of elements in the group $\mathbf{G}$ (order of the group, $|\mathbf{G}|$).
3. There is an orthogonality relation between the different irreducible representations of a group (denoted by a Greek letter as a left superscript):

$$\sum_{\mathbf{g}} {}^{\alpha}G(\mathbf{g})_{ij}^* {}^{\beta}G(\mathbf{g})_{kl} = (|\mathbf{G}|/|{}^{\alpha}G|) \delta_{\alpha\beta} \delta_{ik} \delta_{jl} \quad [14]$$

where $|{}^{\alpha}G|$ is the dimension of the irreducible representation α .

Characters

Let the matrices ${}^{\alpha}G(\mathbf{g})$ form a (reducible or irreducible) representation of a group. The trace of matrix ${}^{\alpha}G(\mathbf{g})$ is called the *character* of the operation $\mathbf{g}_i$ in the representation ${}^{\alpha}G(\mathbf{g})$:

$${}^{\alpha}\chi(\mathbf{g}) = \sum_i {}^{\alpha}G(\mathbf{g})_{ii} \quad [15]$$

An orthogonality relation corresponding to eqn [14] also exists for the characters of irreducible representations:

$$\sum_{\mathbf{g}} {}^{\alpha}\chi(\mathbf{g})^* {}^{\beta}\chi(\mathbf{g}) = |\mathbf{G}| \delta_{\alpha\beta} \quad [16]$$

Symmetrization of states

One of the most important applications of group theoretical methods in quantum mechanics consists of the task to construct so-called *symmetrized* states which by definition not only form an orthonormalized basis of $\mathbf{G}$ -invariant carrier space but also have a peculiar transformation law with respect to the group $\mathbf{G}$. Let $\mathcal{H}$ be a $\mathbf{G}$ -invariant carrier space which for the sake of simplicity implies that $U(\mathbf{G})$ forms a unitary operator representation on $\mathcal{H}$ and that there exists an orthonormalized basis $\Phi = \{\phi_j^s | \alpha \in A_G, s=1, 2, \dots, m_{\alpha}, j=1, 2, \dots, |{}^{\alpha}G|\}$ with the following properties:

$$\langle \phi_j^s, \phi_k^t \rangle = \delta_{\alpha\beta} \delta_{st} \delta_{jk} \quad [17]$$

$$U(\mathbf{g}) \phi_j^s = \sum_{k=1}^{|{}^{\alpha}G|} {}^{\alpha}G(\mathbf{g})_{kj}^s \phi_k^s \quad [18]$$

Here it should be remarked that the symbol $\langle \phi, \psi \rangle$ denotes the scalar product in $\mathcal{H}$ and that A_G symbolizes the index set of the labels which characterize the irreducible $\mathbf{G}$ -representations, and that the index $s=1, 2, \dots, m_{\alpha}$ indicates the frequency of the irreducible representations ${}^{\alpha}G$ in $\mathcal{H}$, respectively.

Usually, the symmetrization of states is carried out by means of a specific projection method which mainly relies upon the properties of the underlying *group algebra*. Without going into any details, we merely state the form and properties of the so-called *units* of the group algebra. The units of the group algebra are represented in the Hilbert space $\mathcal{H}$ by the following operators:

$$P_{jk}^{\alpha} = \frac{|{}^{\alpha}G|}{|\mathbf{G}|} \sum_{\mathbf{g}} {}^{\alpha}G(\mathbf{g})_{jk}^* U(\mathbf{g}) \quad [19]$$

whose properties are well known. Note that P_{jj}^{α} are projection operators, whereas P_{jk}^{α} with $j \neq k$ are shift operators. For further details the reader is referred to the relevant literature. However in this context it is worth emphasizing that there exist some modifications of this method. In particular, it is possible to construct complete sets of commuting operators instead of the units of the group algebra. This method deserves extra attention since it circumvents the representation dependence of the units by solving simultaneous eigenvalue equations.

Spherical harmonics – irreducible $\mathbf{SO}(3, \mathbb{R})$ -representations

The most prominent functions of mathematical physics with applications in many areas of physics and related disciplines are the so-called *spherical harmonics* which form a basis of the Hilbert space $L^2(S)$ where the symbol S denotes the unit sphere. Spherical harmonics are eigenfunctions of the angular momentum operators L^2 and L_z , respectively. For integer values of l the spherical harmonics take the following form where, in particular, the Condon–Shortley phase convention has been adopted:

$$Y_l^m(\theta, \phi) = N_{lm} P_{lm}(\theta) \exp(im\phi) \quad [20]$$

$$N_{lm} = i^{m+|m|} \left\{ \frac{(2l+1)(l-|m|)!}{4\pi(l+|m|)!} \right\}^{1/2} \quad [21]$$

$$P_{lm}(\theta) = \frac{1}{2^l l!} \sin^{|m|} \theta \frac{d^{l+|m|}(\cos^2 \theta - 1)^l}{d(\cos \theta)^{l+|m|}} \quad [22]$$

The group elements $(\omega) \in \mathbf{SO}(3, \mathbb{R})$ are represented in the specific Hilbert space $L^2(S)$ in principle by the same unitary operators as given in eqn [7] though the corresponding Hilbert spaces are different. The matrix elements

of the $(2l+1)$ -dimensional irreducible representations of $\mathbf{SO}(3, \mathbb{R})$ are given by:

$$U(\omega)Y_{lm} = \sum_{m'} R_{m'm}^l(\omega)Y_{lm'} \quad [23]$$

$$R_{m'm}^l(\omega) = \exp\{-i(m'\alpha + m\gamma)\}d_{m'm}^l(\beta) \quad [24]$$

$$\begin{aligned} d_{m'm}^l(\beta) &= \{(l+m')!(l-m')!(l+m)!(l-m)!\}^{1/2} \\ &\times \sum_k (-1)^{k+m'-m} \\ &\times \frac{\cos^{2l-m'+m-2k}(\beta/2) \sin^{2l+m'-m}(\beta/2)}{(l-m'-k)!(l+m-k)!(m'-m+k)!k!} \end{aligned} \quad [25]$$

Equation [24] is also valid for the half-integral values j so that direct products of representations needed for the coupling of arbitrary angular momenta can be calculated. However, one should be aware that for half-integral values j the spherical harmonics due to their definition cannot serve as basis for the corresponding $\mathbf{SU}(2)$ -representations.

Direct Products of Representations

Let $\mathcal{H}_{12}^{\alpha\beta} = \mathcal{H}_1^\alpha \otimes \mathcal{H}_2^\beta$ be the carrier space of the direct product group $\mathbf{G} \times \mathbf{G}$ where the latter contains $\mathbf{G} \boxtimes \mathbf{G}$ as a diagonal subgroup. Let us assume that $\mathcal{H}_1^\alpha$ is the carrier space for the irreducible representations ${}^\alpha G$ and $\mathcal{H}_2^\beta$ is the carrier space for the irreducible representations ${}^\beta G$, respectively. In other words, we assume symmetrized basis functions ${}^\alpha\varphi_i$, $i=1, 2, \dots, |{}^\alpha G|$ of $\mathcal{H}_1^\alpha$ and equivalently symmetrized basis functions ${}^\beta\psi_j$, $j=1, 2, \dots, |{}^\beta G|$ of $\mathcal{H}_2^\beta$, respectively. The group elements $(g_1, g_2) \in \mathbf{G} \times \mathbf{G}$ are represented by the unitary operators $U(g_1, g_2) = U_1(g_1) \otimes U_2(g_2)$ where $U_1(g_1)$ acts nontrivially on $\mathcal{H}_1$ only and similarly $U_2(g_2)$ on $\mathcal{H}_2$, respectively. Now, if all possible products

$$\Psi_{ij}^{\alpha,\beta} = \varphi_i \otimes \psi_j \quad [26]$$

are formed, then an orthonormal basis of the product space $\mathcal{H}_{12}^{\alpha\beta}$ is defined, since the factor bases $\{\varphi_i\}$ and $\{\psi_j\}$ are assumed to be symmetrized ones. This allows one to define for the Kronecker product group $\mathbf{G} \boxtimes \mathbf{G}$ a unitary $|{}^\alpha G| \times |{}^\beta G|$ -dimensional matrix representation (in general reducible) which is of the following form:

$$U(g, g)\Psi_{ij}^{\alpha,\beta} = \sum_{rs} G^{\alpha,\beta}(g)_{rs,ij} \Psi_{rs}^{\alpha,\beta} \quad [27]$$

$$G^{\alpha,\beta}(g) = {}^\alpha G(g) \otimes {}^\beta G(g) \quad [28]$$

This representation is called the *direct product* of the representations ${}^\alpha G$ and ${}^\beta G$. It can be decomposed into the so-called *direct sum* of its irreducible constituents, say ${}^\sigma G$,

of $\mathbf{G}$ written symbolically as:

$$G^{\alpha,\beta}(g) = \sum_{\sigma} \oplus a_{\alpha\beta;\sigma} {}^\sigma G(g) \quad [29]$$

$$\begin{aligned} a_{\alpha\beta;\sigma} &= |\mathbf{G}|^{-1} \sum_g {}^{\alpha \times \beta} \chi(g) {}^\sigma \chi(g)^* \\ &= |\mathbf{G}|^{-1} \sum_g {}^\alpha \chi(g) {}^\beta \chi(g) {}^\sigma \chi(g)^* \end{aligned} \quad [30]$$

The coefficients $a_{\alpha\beta;\sigma}$ indicate how often the irreducible representation ${}^\sigma G$ is contained in the direct product (*multiplicity* or *frequency*).

Clebsch–Gordan coefficients

The canonical basis for the irreducible representation ${}^\sigma G$ in eqn [29] is given by the set of functions ${}^\sigma \Phi_k^q$, $k=1, 2, \dots, |{}^\sigma G|$, where the index $q=1, 2, \dots, a_\sigma$ indicates how many times ${}^\sigma G$ is contained in ${}^\alpha G \otimes {}^\beta G$. The functions ${}^\sigma \Phi_k^q$ can be expressed as linear combinations of the products ${}^\alpha\varphi_i \otimes {}^\beta\psi_j = \Psi_{ij}^{\alpha\beta}$:

$${}^\sigma \Phi_k^q = \sum_{ij} \Psi_{ij}^{\alpha\beta} \langle \alpha i, \beta j | \sigma q k \rangle \quad [31]$$

The linear-combination coefficients $\langle \alpha i, \beta j | \sigma q k \rangle$ are commonly called *Clebsch–Gordan coefficients*. The Clebsch–Gordan coefficients form a unitary matrix $C^{\alpha\beta}$ whose columns are given by the following expressions and are satisfying specific transformation laws which allow their systematic computation:

$$\{\vec{C}_{\sigma q k}^{\alpha\beta}\}_{ij} = \langle \alpha i, \beta j | \sigma q k \rangle \quad [32]$$

$$G^{\alpha,\beta}(g) \vec{C}_{\sigma q k}^{\alpha,\beta} = \sum_m {}^\sigma G(g)_{mk} \vec{C}_{\sigma q m}^{\alpha,\beta} \quad [33]$$

Here, it is worth emphasizing that Clebsch–Gordan matrices $C^{\alpha\beta}$ are nonsymmetrically indexed, since their rows are labelled by the pairs (i, j) whereas their columns are labelled by the triplets (σ, q, k) , respectively. The inverse form of eqn [31] is given by the following expression:

$$\Psi_{ij}^{\alpha\beta} = \sum_{\sigma q k} {}^\sigma \Phi_k^q \langle \sigma q k | \alpha i, \beta j \rangle \quad [34]$$

3nj Symbols and Atomic Spectra

Clebsch–Gordan Coefficients and Wigner's 3j Symbols: Coupling of Two Angular Momenta

We now consider the coupling of two angular momenta. For this purpose we have to specify eqn [31] to the case

$\mathbf{G} = \mathbf{SU}(2)$ which is here written as:

$$|(j_1 j_2)jm\rangle = \sum_{m_1, m_2} |j_1 m_1 j_2 m_2\rangle \langle j_1 m_1 j_2 m_2 | jm\rangle \quad [35]$$

First, it should be noted that the states $|j_1, m_1\rangle = \phi_{j_1, m_1}^{\lambda_1}$ and similarly $|j_2, m_2\rangle = \phi_{j_2, m_2}^{\lambda_2}$ are written in a shorthand notation where the principal quantum numbers λ_1, λ_2 are suppressed. Accordingly, the irreducible representation labels are j_1 and j_2 for the uncoupled representations and j for the coupled representations. The index m ($-j \leq m \leq j$) numbers the different functions of the basis. For the products of the uncoupled functions $|j_1, m_1\rangle \otimes |j_2, m_2\rangle$ we simply write $|j_1 m_1 j_2 m_2\rangle$ for short. The multiplicity index of eqn [31] can be dropped here, because in the special unitary group $\mathbf{SU}(2)$ each irreducible representation occurs exactly once in the direct product. It should be noticed that a variety of different symbols are in use in the literature for the Clebsch–Gordan coefficients and different phase conventions exist. Because of

$$m_1 + m_2 = m \quad [36]$$

$$j_1 + j_2 \geq j \geq |j_1 - j_2| \quad [37]$$

the sum (eqn [35]) is only formally a double sum since the condition (eqn [36]) must hold and for given values j_1 and j_2 the range of variation of j -values is determined by the triangle inequality (eqn [37]) respectively.

Finally, we emphasize that the Clebsch–Gordan coefficients for $\mathbf{SU}(2)$ are directly related to the Wigner's $3j$ symbols where the latter have the advantage of being more symmetric than the former.

$$\begin{aligned} \langle j_1 m_1 j_2 m_2 | jm\rangle &= (2j+1)^{1/2} (-1)^{-j_1+j_2-m} \\ &\times \begin{pmatrix} j_1 & j_2 & j \\ m_1 & m_2 & -m \end{pmatrix}. \end{aligned} \quad [38]$$

Calculation and Symmetry Properties of the $3j$ Symbols

The following general formula for the calculation of $3j$ symbols is due to Racah:

$$\begin{aligned} &\begin{pmatrix} a & b & c \\ \alpha & \beta & \gamma \end{pmatrix} \\ &= (-1)^{a-b-\gamma} F(abc) \{(a+\alpha)!(a-\alpha)!(b+\beta)! \\ &\times (b-\beta)!(c+\gamma)!(c-\gamma)!\}^{1/2} \\ &\times \sum_k (-1)^k \{k!(a+b-c-k)!(a-\alpha-k)! \\ &\times (b+\beta-k)!(-b+c+\alpha+k)! \\ &\times (-a+c+\beta+k)!\}^{-1} \end{aligned} \quad [39]$$

$$F(abc) = \left\{ \frac{(-a+b+c)!(a-b+c)!(a+b-c)!}{(a+b+c+1)!} \right\}^{1/2} \quad [40]$$

where the summation over k extends over all values for which all the factorials are defined. It is valid for $\alpha + \beta + \gamma = 0$ and $\Delta(abc) = 1$ (the latter being a compact notation for the triangle condition (eqn [37]) otherwise the $3j$ symbols vanish by definition. Much simpler formulae exist for some of the special cases.

The $3j$ symbols have a high degree of symmetry. Many (but not all) of these symmetries can be seen by using a highly redundant notation which was introduced initially by Regge:

$$\begin{pmatrix} a & b & c \\ \alpha & \beta & \gamma \end{pmatrix} = \begin{bmatrix} -a+b+c & a-b+c & a+b-c \\ a+\alpha & b+\beta & c+\gamma \\ a-\alpha & b-\beta & c-\gamma \end{bmatrix} \quad [41]$$

The following operations performed on the square-bracket Regge symbol define 72 symmetries of the $3j$ symbol:

- (i) Permutations of the columns. The symbol is multiplied by $(-1)^{a+b+c}$ if the permutation is odd.
- (ii) Permutations of the rows. As in (i) the symbol is multiplied by $(-1)^{a+b+c}$ if the permutation is odd.
- (iii) Transposition about the main diagonal (like the transposition of an ordinary matrix).

Coupling of Three Angular Momenta

If three angular momenta $\mathbf{J}_1, \mathbf{J}_2, \mathbf{J}_3$ have to be coupled to the total angular momentum $\mathbf{J}$ there are different ways leading to bases related to each other by a unitary transformation. One possibility is to start from the uncoupled state $|j_1 m_1 j_2 m_2 j_3 m_3\rangle$ and to perform first of all the coupling $\mathbf{J}_1 + \mathbf{J}_2 = \mathbf{J}_{12}$ and then $\mathbf{J}_{12} + \mathbf{J}_3 = \mathbf{J}$ leading to a coupled state denoted as $|((j_1 j_2) j_{12} j_3) jm\rangle$. Another possibility is the coupling scheme $\mathbf{J}_2 + \mathbf{J}_3 = \mathbf{J}_{23} = \mathbf{J}_1 + \mathbf{J}_{23} = \mathbf{J}$ with the corresponding wavefunction $|j_1 (j_2 j_3) j_{23} jm\rangle$. With these definitions the following relations between the two types of state functions hold:

$$|((j_1 j_2) j_{12} j_3) jm\rangle = \sum_{j_{23}} |j_1 (j_2 j_3) j_{23} jm\rangle V_{j_{23} j_{12}}^{(j)} \quad [42]$$

$$V_{j_{23} j_{12}}^{(j)} = \langle j_1 (j_2 j_3) j_{23} jm | ((j_1 j_2) j_{12} j_3) jm \rangle \quad [43]$$

The coefficients $V_{j_{23} j_{12}}^{(j)}$, which only depend on the values of the j s but are independent of m , are called *recoupling coefficients* and can be expressed in terms of Clebsch–Gordan coefficients:

$$\begin{aligned} V_{j_{23} j_{12}}^{(j)} &= \sum_{\text{all } m_i} \langle j_2 m_2 j_3 m_3 | j_{23} m_{23} \rangle \langle j_1 m_1 j_{23} m_{23} | jm \rangle \\ &\times \langle j_1 m_1 j_2 m_2 | j_{12} m_{12} \rangle \langle j_{12} m_{12} j_3 m_3 | jm \rangle \end{aligned} \quad [44]$$

Analogous to the introduction of the $3j$ symbols (eqn [38]) one defines $6j$ symbols:

$$V_{j_2 j_3 j_1}^{(j)} = \{(2j_{23} + 1)(2j_{12} + 1)\}^{1/2} (-1)^{j_1 + j_2 + j_3 + j} \times \begin{Bmatrix} j_1 & j_2 & j_{12} \\ j_3 & j & j_{23} \end{Bmatrix} \quad [45]$$

Equation [41] can thus be written as:

$$\begin{Bmatrix} j_1 & j_2 & j_3 \\ l_1 & l_2 & l_3 \end{Bmatrix} = \sum_{\substack{\text{all } \mu_1 \\ \text{all } \mu_2 \\ \text{all } \mu_3}} (-1)^s \left[\begin{pmatrix} j_1 & j_2 & j_3 \\ m_1 & m_2 & m_3 \end{pmatrix} \begin{pmatrix} j_1 & l_2 & l_3 \\ m_1 & \mu_2 & -\mu_3 \end{pmatrix} \times \begin{pmatrix} l_1 & j_2 & l_3 \\ -\mu_1 & m_2 & \mu_3 \end{pmatrix} \begin{pmatrix} l_1 & l_2 & j_3 \\ \mu_1 & -\mu_2 & m_3 \end{pmatrix} \right] \quad [46]$$

where $s = l_1 + l_2 + l_3 + \mu_1 + \mu_2 + \mu_3$.

Calculation and Symmetry Properties of the $6j$ -Symbols

With the abbreviation (eqn [40]) Racah's formula for the $6j$ coefficients reads:

$$\begin{Bmatrix} a & b & c \\ d & e & f \end{Bmatrix} = F(abc)F(aef)F(dbf)F(dec) \times \sum_k \left\{ \frac{(-1)^k (k+1)!}{(a+b+d+e-k)!(b+c+e+f-k)!(a+c+d+f-k)!} \times \frac{1}{(k-a-b-c)!(k-a-e-f)!(k-b-d-f)!(k-d-e-c)!} \right\} \quad [47]$$

The $6j$ symbols are invariant under interchange of the columns. A further invariance exists with respect to the interchange of any two numbers from the top row with their counterparts in the bottom row, e.g.:

$$\begin{Bmatrix} j_1 & j_2 & j_3 \\ l_1 & l_2 & l_3 \end{Bmatrix} = \begin{Bmatrix} j_1 & l_2 & l_3 \\ l_1 & j_2 & j_3 \end{Bmatrix} \quad [48]$$

The $6j$ symbols are different from zero only if the following four triangle conditions are fulfilled:

$$\Delta(j_1 j_2 j_3) = \Delta(j_1 l_2 l_3) = \Delta(l_1 j_2 j_3) = \Delta(l_1 l_2 j_3) = 1 \quad [49]$$

and if the sum of the side lengths of these triangles are integers. Further symmetries of the $6j$ symbols have been found but they are not discussed here.

9j and 12j Symbols

The $9j$ symbols are required for the coupling of four angular momenta. An example is the coupling of two orbital and two spin angular momenta either within the Russel–Saunders (LS) or the jj coupling scheme. The $9j$ symbols can also be used as recoupling coefficients for the transformation from one of the two schemes into the other. They can be expressed in terms of $3j$ or $6j$ symbols. Analogously, the coupling between five angular momenta can be described by the $12j$ symbols for which formulae in terms of $6j$ and $9j$ symbols exist.

Property Tensors and Vibrational Spectra of Crystals

Property Tensors

Like other physical objects, as, for example, elementary particles, atoms and molecules, crystals are characterized by their symmetry which, as has been known now for more than a century, has a determining influence on their physical properties. The underlying symmetry principle, often called the ‘Neumann–Minnigerode–Curie principle’, can, for our purposes, be written as:

$$G_{\text{object}} \subseteq G_{\text{property}} \quad [50]$$

where G_{object} is the symmetry group of the object and G_{property} the symmetry group of the physical property. Therefore the symmetry operations for the crystal are also valid symmetry operations for its physical properties.

On the other hand, crystals are media that are anisotropic, which means that the application of certain forces onto the crystal (e.g. by an electric field) leads to a response or an effect (like the induced polarization) which depends on the orientation of the crystal. Both quantities, the electric field $\mathbf{E}$ and the electric polarization $\mathbf{P}$, are vectors which, in general, point in different directions. For sufficiently low electric fields this leads to a linear relationship between the electric field and the electric polarization, which can be written as tensor

equations as follows:

$$\mathbf{P} = \chi \mathbf{E} \quad [51]$$

$$\begin{aligned} P_x &= \chi_{xx} E_x + \chi_{xy} E_y + \chi_{xz} E_z \\ P_y &= \chi_{yx} E_x + \chi_{yy} E_y + \chi_{yz} E_z \\ P_z &= \chi_{zx} E_x + \chi_{zy} E_y + \chi_{zz} E_z \end{aligned} \quad [52]$$

$$P_i = \chi_{ij} E_j \quad [53]$$

Note that eqn [51] represents formally the tensorial relationship, while eqn [52] expresses this relation by the (Cartesian) components of $\mathbf{P}$ and $\mathbf{E}$ and some coefficients χ_{ij} , whereas eqn [53] states this relation by using Einstein's summation convention. Here, the coefficients χ_{ij} are the components of the electric susceptibility tensor which is a tensor of rank 2. The tensor χ is an example of what is usually called a *property tensor* or *matter tensor*. Strictly speaking, property tensors describe physical properties of the static crystal which belong to the totally symmetric irreducible representation of the relevant point group. Properties, however, that depend on vibrations of the crystal lattice are described by tensors which belong to the different irreducible representations. The corresponding tensors are then often designated as *tensorial covariants*.

If the electric field is not low enough for a linear relationship (eqn [53]) to hold higher-order terms become important:

$$P_i = \chi_{ij}^{(1)} E_j + \frac{1}{2} \chi_{ijk}^{(2)} E_k E_j + \frac{1}{6} \chi_{ijkl}^{(3)} E_l E_k E_j + \dots \quad [54]$$

While $\chi^{(1)}$ is important for the Raman effect, the electric susceptibilities of higher order ($\chi^{(2)}$, $\chi^{(3)}$, etc.) are tensors of ranks 3, 4, etc., and are necessary for the description of the hyper-Raman effect.

All tensors can be classified by their parity, i.e. by their behaviour under the symmetry operation of the inversion of the space. Tensors (like vectors) are said to have even parity if they remain unchanged under space inversion and have odd parity if they change sign. In a tensor equation such as eqn [54], the parities on both sides of the equations must be the same. Thus, since $\mathbf{E}$ and $\mathbf{P}$ have odd parity, the parity of the susceptibility tensor must be even. Instead of using the term 'parity' one usually designates tensors as *polar tensors* (tensors of even rank having even parity or tensors of odd rank having odd parity) or *axial tensors* (tensors of odd rank having even parity or tensors of even rank having odd parity).

A further criterion for the classification of tensors is their behaviour under time reversal. This is important when one is interested in magnetic properties, for instance in the Raman effect of magnetic crystals. All tensors we are dealing with in this section are assumed to be invariant under time reversal. The latter are also known in the literature as *i-tensors*.

In addition to the above-mentioned classification, a property tensor may have an *intrinsic symmetry*, i.e. a symmetry with respect to the interchange of certain indices which is determined by the symmetry properties of the tensors for the cause and for the effect.

Transformation Properties of Tensors of Rank $[m]$

Here we consider the *Euclidean* vector space $\mathbb{E}^3 \simeq \mathbb{R}^3$ and assume that the components of an arbitrary vector $\mathbb{R}^3$ are its Cartesian components with respect to a fixed orthonormal basis where the former are denoted by $x_1 = x$, $x_2 = y$, $x_3 = z$, respectively. Accordingly a tensor of rank $[m]$ is defined as follows:

$$\left\{ \mathbf{T}^{[m]} \right\}_{i_1, i_2, \dots, i_m} = x_{i_1} x_{i_2} \dots x_{i_m} \quad [55]$$

$$\mathbf{T}^{[m]'} = \mathbf{g} \mathbf{T}^{[m]} \quad [56]$$

$$\mathbf{g} \mathbf{T}^{[m]} = \mathbf{M}^{[m]}(\mathbf{g}) \mathbf{T}^{[m]} \quad [57]$$

$$\mathbf{M}^{[m]}(\mathbf{g}) = M(\mathbf{g}) \otimes M(\mathbf{g}) \otimes \dots \otimes M(\mathbf{g}) \quad [58]$$

$$\left\{ \mathbf{T}^{[m]'} \right\}_{i_1, i_2, \dots, i_m} = M_{i_1 j_1}(\mathbf{g}) M_{i_2 j_2}(\mathbf{g}) \dots M_{i_m j_m}(\mathbf{g}) \left\{ \mathbf{T}^{[m]} \right\}_{j_1, j_2, \dots, j_m} \quad [59]$$

Here the entries $\left\{ \mathbf{T}^{[m]} \right\}_{i_1, i_2, \dots, i_m}$ denote the Cartesian components of the tensor of rank $[m]$ where $i_j = 1, 2, 3$ has to be taken into account. Equations [56] to [58] describe the transformation properties of an arbitrary tensor of rank $[m]$ with respect to the orthogonal group $\mathbf{O}(3, \mathbb{R})$, respectively. The matrix group $\mathbf{M}^{[m]}$ is the m -fold tensor representation of $\mathbf{O}(3, \mathbb{R})$, where $M(\mathbf{g})$ is a real 3-dimensional matrix representation of $\mathbf{g} \in \mathbf{O}(3, \mathbb{R})$, which implies that $\mathbf{M}^{[m]}$ defines a real 3^m -dimensional $\mathbf{O}(3, \mathbb{R})$ -representation. Moreover, note that in eqn [59] Einstein's summation convention has been used. Finally, one has to distinguish carefully between *polar* and *axial* tensors of rank $[m]$ since their inherent transformation properties with respect to $\mathbf{O}(3, \mathbb{R})$, being stated below, are significantly different.

$$\mathbf{g} \mathbf{T}_{\text{polar}}^{[m]} = \mathbf{M}^{[m]}(\mathbf{g}) \mathbf{T}_{\text{polar}}^{[m]} \quad [60]$$

$$\mathbf{g} \mathbf{T}_{\text{axial}}^{[m]} = (\Delta(\mathbf{g}))^m \mathbf{M}^{[m]}(\mathbf{g}) \mathbf{T}_{\text{axial}}^{[m]} \quad [61]$$

$$\Delta(\mathbf{g}) = \det M(\mathbf{g}) \quad [62]$$

Here it is important to notice that $\Delta(\mathbf{g}) = \det M(\mathbf{g}) = +1$ for proper rotations and $\Delta(\mathbf{g}) = \det M(\mathbf{g}) = -1$ for improper rotations, like for the inversion or reflections. Thus, the factor $(\Delta(\mathbf{g}))^m$ occurring in eqn [61] is the m -th

power of this phase factor and confirms what has been stated in the preceding section as regards the transformation properties of tensors with respect to the space inversion.

Calculation of Property Tensors (Tensorial Covariants)

Property tensors of arbitrary rank $[m]$ can be constructed by symmetry adapting their Cartesian components along the lines of the well-known projection method where the group $\mathbf{G}$ is assumed to be a finite subgroup of $\mathbf{O}(3, \mathbb{R})$. In other words, here the symmetry adaptation of the tensors is carried out for point groups and some nontrivial extensions like for magnetic point groups, which we discuss later. The procedure can be divided into several steps. First, the projection operators are defined, and second, they are applied to the Cartesian tensors, and finally the shift operators are applied to the symmetrized tensors to obtain the corresponding partner tensors. The procedure is summarized as follows:

$$^{[m]}P_{ij}^{\gamma} = |^{\gamma}G| |\mathbf{G}|^{-1} \sum_g {}^{\gamma}G(g)_{ij}^* g \quad [63]$$

$$^{[m]}X_i^{\gamma} = ^{[m]}P_{ii}^{\gamma} T^{[m]} \quad [64]$$

$$^{[m]}X_j^{\gamma} = ^{[m]}P_{ji}^{\gamma} T^{[m]} \quad [65]$$

Several remarks are necessary. The units $^{[m]}P_{ij}^{\gamma}$ of the corresponding group algebra are provided with the superscript $[m]$ in order to indicate that their representation is realized in the space of tensors of rank $[m]$, respectively. The first step is to use eqn [64] in order to generate just one tensor for the $|^{\gamma}G|$ -dimensional irreducible representation. In fact, the number of free parameters must coincide with the frequency of $^{\gamma}G$ in the reducible tensor representation $\mathbf{M}^{[m]}$. The other tensors of a multidimensional tensor basis are obtained from eqn [64] by applying the appropriate shift operators. The given formulae are valid for the calculation of polar and axial tensors, since one merely has to use either eqn [60] for polar tensors or eqn [61] together with eqn [62] for axial tensors, respectively. For the sake of clarity, the explicit forms of the calculated tensors the following notation is used in order to define tensors of rank 2 and rank 3 in matrix form:

$$T^{[2]} = \begin{bmatrix} xx & xy & xz \\ yx & yy & yz \\ zx & zy & zz \end{bmatrix} \quad [66]$$

$$T^{[3]} = \begin{bmatrix} xxx & xxy & xxz \\ xyx & xyy & xyz \\ xzx & xzy & xzz \\ - & - & - \\ yxx & yxy & yxz \\ yyx & yyy & yyz \\ yzx & yzy & yzz \\ - & - & - \\ zxx & zxy & zxz \\ zyx & zyy & zyz \\ zzx & zzy & zzz \end{bmatrix} \quad [67]$$

Since the components of property tensors are quantities that can be measured experimentally, they have to be real. The results obtained from eqns [64] and [65] are real, if real rotation matrices and real irreducible representations are used. The latter can always be achieved for the multidimensional representations. However, there are 10 crystallographic point groups which have pairs of one-dimensional irreducible representations complex conjugate to each other. In a case like this, one first computes pairs of conjugate complex tensors and then forms two real linear combinations for each conjugate pair as illustrated below for $\mathbf{C}_3$ (or 3 in Hermann–Mauguin notation).

Polar tensors of rank 2 for group $\mathbf{C}_3$

The characters for $\mathbf{C}_3$ are shown in Table 1 and the required rotation matrix for the operation C_3^+ can be taken from Table 4 (the matrix for C_3^- is the square of the matrix for C_3^+). With these data the polar tensors of rank 2 can be calculated. Using the abbreviations $a = xx + yy$, $b = xy - yx$, $c = zz$, $d = \frac{1}{2}(xx - yy)$, $e = \frac{1}{2}(xy + yx)$, $f = xz$, $g = yz$, $h = zx$ and $j = zy$, the resulting tensors that are complex for the representations 1E and 2E are displayed in Table 2. Adding the two tensors for 1E and 2E gives the first real tensor and multiplying the one for 1E with $-i$ and the one for 2E with i and adding them together gives the second real tensor for the ‘physically irreducible representation’ E , as it is sometimes called (see Table 3).

A note on magnetic point groups

In order to describe consistently some properties of magnetic systems that are related to their symmetry, the concept of ordinary point groups was extended, to so-called *magnetic* point groups. In order to cope with these types of problems a new operation has been introduced designated as *antisymmetry operation*. The latter does not

affect the space coordinates but only reverses the sign of the magnetic moment at each point in space. Instead of ordinary point groups one has to deal with magnetic point groups (colour groups) in which some of the ordinary point-group operations appear in combination with the antisymmetry operation. To summarize, one can also construct symmetry adapted tensors for magnetic point groups, where the crucial difference consists of a certain modification of the transformation formulae (eqns [60] to [62]).

Raman and hyper-Raman tensors for Laue class $\bar{3}m$

Here, the Raman and the hyper-Raman tensors for trigonal lattices shall be given. The property tensor for the Raman effect is the derivative of the polarizability with respect to the normal coordinate and is a polar second rank i -tensor which is symmetric if the resonant Raman effect or a degenerate ground state are excluded while the corresponding tensor for the hyper-Raman effect is a polar i -tensor of rank three the internal symmetry of which is dependent on the experimental conditions.

The matrix generators for the groups belonging to this Laue class, namely D_3 (32), C_{3v} ($3m$) and D_{3d} ($\bar{3}m$), are shown in **Table 4** and the representation matrices (in real form) for the generators in **Table 5** (the information for D_{3d} can easily be generated by forming the direct product $D_{3d} = D_3 \times C_i$ where $C_i = \{E, i\}$).

The obtained tensors (here given without any intrinsic symmetry) are displayed in **Table 6** where for the tensors of rank 2 the two numbers on the right-hand side of

$\mathbf{P}_2 = \begin{bmatrix} a & 0 & 0 \\ 0 & a & 0 \\ 0 & 0 & b \end{bmatrix} \begin{matrix} 2 \\ 2 \end{matrix}$	$\mathbf{Q}_2 = \begin{bmatrix} 0 & c & 0 \\ -c & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix} \begin{matrix} 1 \\ 0 \end{matrix}$
$\mathbf{R}_2^{(1)} = \begin{bmatrix} d & 0 & 0 \\ 0 & -d & e \\ 0 & f & 0 \end{bmatrix} \begin{matrix} 3 \\ 2 \end{matrix}$	$\mathbf{R}_2^{(2)} = \begin{bmatrix} 0 & -d & -e \\ -d & 0 & 0 \\ -f & 0 & 0 \end{bmatrix} \begin{matrix} 3 \\ 2 \end{matrix}$
$\mathbf{P}_3 = \begin{bmatrix} a & 0 & 0 \\ 0 & -a & b \\ 0 & c & 0 \\ - & - & - \\ 0 & -a & -b \\ -a & 0 & 0 \\ -c & 0 & 0 \\ - & - & - \\ 0 & d & 0 \\ -d & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix} \begin{matrix} 4 \\ 2 \\ 1 \end{matrix}$	$\mathbf{Q}_3 = \begin{bmatrix} 0 & e & f \\ e & 0 & 0 \\ g & 0 & 0 \\ - & - & - \\ e & 0 & 0 \\ 0 & -e & f \\ 0 & g & 0 \\ - & - & - \\ h & 0 & 0 \\ 0 & h & 0 \\ 0 & 0 & i \end{bmatrix} \begin{matrix} 5 \\ 4 \\ 3 \end{matrix}$
$\mathbf{R}_3^{(1)} = \begin{bmatrix} j+k+l & 0 & 0 \\ 0 & j & m \\ 0 & n & p \\ - & - & - \\ 0 & k & m \\ l & 0 & 0 \\ n & 0 & 0 \\ - & - & - \\ 0 & q & r \\ q & 0 & 0 \\ s & 0 & 0 \end{bmatrix} \begin{matrix} 9 \\ 6 \\ 3 \end{matrix}$	$\mathbf{R}_3^{(2)} = \begin{bmatrix} 0 & l & m \\ k & 0 & 0 \\ n & 0 & 0 \\ - & - & - \\ j & 0 & 0 \\ 0 & j+k+l & -m \\ 0 & -n & p \\ - & - & - \\ q & 0 & 0 \\ 0 & -q & r \\ 0 & s & 0 \end{bmatrix} \begin{matrix} 9 \\ 6 \\ 3 \end{matrix}$

the matrices give the numbers of independent components of the tensor without any intrinsic symmetry and for the symmetric tensor, respectively. Summing these numbers for all irreducible representations must give 9 (the number of components of a general tensor of rank 2 without intrinsic symmetry) and 6 (the number of components of a symmetric tensor of rank 2). For the tensors

of rank 3 the numbers of independent components without intrinsic symmetry, for intrinsic symmetry with respect to the interchange of two indices and for the totally symmetric tensor are indicated in a similar fashion. The corresponding sums over the irreducible representations must yield 27, 18 and 10 in this case taking into account the required intrinsic symmetries. In **Table 7** the Raman and hyper-Raman tensors for the Laue class $\bar{3}m$ are displayed.

Selection Rules

In order to determine whether a transition between given initial and final states is allowed or forbidden, one only has to know whether the following scalar product is zero or not:

$$\langle \Psi_i^\alpha, O_k^\gamma \Psi_j^\beta \rangle = \int_{\mathbb{R}^3} d^3x \Psi_i^\alpha(\vec{x})^* O_k^\gamma \Psi_j^\beta(\vec{x}) \quad [68]$$

where the operator O_k^γ is the electric dipole moment, the electric susceptibility or the electric susceptibility of second order, depending on whether infrared absorption, Raman or hyper-Raman scattering is to be investigated and Ψ_i^α and Ψ_j^β are the initial and final states, respectively. The integral (eqn [68]) is different from zero only if the totally symmetric irreducible representation is contained in the direct product representation ${}^\alpha G^* \otimes {}^\beta G \otimes {}^\gamma G$. According to eqn [30], this is the case if the corresponding frequency number

$$a_{\gamma\beta;\alpha} = |G|^{-1} \sum_g {}^\alpha \chi(g)^* {}^\gamma \chi(g) {}^\beta \chi(g) \quad [69]$$

is greater than zero. Often, Ψ_j^α belongs to the totally symmetric irreducible representation in which case its characters are all equal to 1.

In order to obtain the characters for the (reducible) representation to which the operator O_k^γ belongs one only has to consider matrices of the form:

$$M(g) = \begin{bmatrix} \cos \phi_g & -\sin \phi_g & 0 \\ \sin \phi_g & \cos \phi_g & 0 \\ 0 & 0 & \pm 1 \end{bmatrix} \quad [70]$$

where the positive sign holds for proper operations (pure rotations about the z axis) and the negative sign for improper operations (rotations combined with reflections about the xy plane).

For infrared absorption O_k^γ is the operator for the electric dipole moment which is a polar vector transforming like the Cartesian coordinates x, y, z . The corresponding character is given by the trace of the matrix (eqn [70]).

$$\chi_{IR}(g) = 2 \cos \phi_g \pm 1 \quad [71]$$

For the Raman effect the operator is that for the electric polarizability which is a polar tensor of rank 2. Without any intrinsic symmetry the character is the square of the trace of the matrix (eqn [70]). However, since we assume a symmetric tensor here, the character becomes:

$$\chi_R(g) = 2 \cos \phi_g (2 \cos \phi_g \pm 1) \quad [72]$$

For the hyper-Raman effect we only consider the case of a totally symmetric polar tensor of rank 3. Under this assumption the character is:

$$\chi_{HR}(g) = 2 \cos \phi_g (4 \cos^2 \phi_g \pm 2 \cos \phi_g - 1) \quad [73]$$

With this information and only using group character tables one can easily find out to which symmetry species Ψ_i^α may belong in order that a transition is observed.

There is a general rule that follows from the symmetry considerations above, called *mutual exclusion rule*: 'In groups having a centre of symmetry the modes active in Raman scattering are inactive in infrared absorption and vice versa'. An explanation for this behaviour is that the property tensor for infrared absorption is a polar vector and for Raman scattering a polar tensor of rank 2. While the parity under space inversion of the former is odd and thus belongs to an *ungerade* representation of the point group, it is even for the latter and belongs to a *gerade* representation.

In Raman spectroscopy the relative intensity of the scattered light is straightforwardly calculated from the appropriate Raman tensor as follows: If $\mathbf{v}_i$ is a unit vector defining the polarization of the incident laser radiation and $\mathbf{v}_s$ a unit vector characterizing the polarization of the scattered light, then the following proportionality for the intensity I of the total scattered radiation holds:

$$I \sim |\mathbf{v}_i \cdot \boldsymbol{\chi} \cdot \mathbf{v}_s|^2 \quad [74]$$

where the inner product has to be formed between the three tensor quantities on the right-hand side. With a suitable experimental arrangement the components of the Raman tensor can thus be measured independently.

Thermospray Ionization in Mass Spectrometry

Introduction

Thermospray ionization is a soft ionization technique, applicable with a thermospray interface for combining liquid chromatography and mass spectrometry (LC-MS). The thermospray interface was developed by Vestal and co-workers at the University of Houston (TX) and subsequently commercialized by Vestal in the company Vestec (Houston, TX). The thermospray interface was the first LC-MS interface, where the analyte ionization is an integral part of the introduction of the column effluent into the mass spectrometer. Between 1987 and 1992, thermospray interfacing and ionization was the most widely used strategy for LC-MS coupling. After 1992, its use diminished in favour of interfacing strategies based on atmospheric-pressure ionization, i.e. electrospray and atmospheric-pressure chemical ionization (APCI).

In a thermospray interface, a jet of vapour and small droplets is formed by heating the column effluent of an LC column or any other continuous liquid stream in a heated vaporizer tube. Nebulization takes place as a result of the disruption of the liquid by the expanding vapour that is formed upon evaporation of part of the liquid in the tube. A considerable amount of heat is transferred to the solvent prior to the onset of the partial inside-tube evaporation. This assists in the desolvation of the droplets in the lower pressure region. By applying efficient pumping directly at the ion source, up to 2 mL min^{-1} of aqueous solvents can be introduced into the MS vacuum system. The ionization of the analytes takes place by mixed mechanisms based on gas-phase ion–molecule reactions and ion evaporation processes. The reagent gas for ionization can be made either in a conventional way using energetic electrons from a filament or discharge electrode, or in a process called thermospray buffer ionization, where the volatile buffer dissolved in the eluent is involved. Thermospray interfacing and ionization as well as its applications in LC-MS have been reviewed in two excellent review papers by Arpino and in two extensive book chapters.

Thermospray Interface

The thermospray interface is the result of a long-term research project between 1978 and 1984, aimed at the development of an LC-MS interface which is compatible

with a flow-rate of 1 mL min^{-1} of an aqueous mobile phase and is capable of providing both electron ionization and chemical ionization mass spectra. Initially, the two most important research topics were related to the ability to (1) achieve a very rapid heating and subsequent vaporization of the column effluent, and to (2) achieve sufficient vacuum conditions to successfully perform analyte ionization and mass analysis, while introducing large amounts of liquid vapour, i.e. the equivalent of 1 mL min^{-1} aqueous solvents. The developments with respect to the various heating systems investigated for the rapid vaporization of the mobile phase from the LC column are summarized in **Table 1**. The highly complex setup of the first prototype, featuring laser vaporization of the mobile phase and an extensive vacuum system containing orthogonal quadrupole analysers, was simplified in subsequent interface designs. The heat required for the evaporation of the 1 mL min^{-1} aqueous mobile phase could, instead of using an expensive laser system, also be provided with an electrically heated vaporizer capillary (see **Table 1**). In addition, the vacuum system could be significantly simplified by connecting a mechanical rotary pump directly to the ion source block. The highly directed flow of the liquid vapour jet from the thermospray vaporizer considerably enhances the pumping efficiency of this pump.

A commercial thermospray interface consists of a direct-electrically heated vaporizer type, mostly fitted into a spray probe, a heated source block featuring a filament, a discharge electrode, a repeller electrode and

Table 1 Characteristics of various heating systems investigated in the development of the thermospray interface

Heat supply	Heated length (mm)	Energy flux (W cm^{-2})	Total power (W)
CO ₂ laser beam focused on liquid jet	0.3	30 000	25
Hydrogen flames to heat a copper cylinder at the capillary exit	3	5 000	50
Indirect electrically heated capillary	30	700	100
Direct electrically heated capillary	300	70	150

an ion-sampling cone to the mass analyser, and the exhaust pump outlet. A schematic diagram of a typical thermospray system is shown in **Figure 1**. The temperature of the vaporizer tube must be accurately controlled in order to ascertain the partial liquid evaporation, required for successful thermospray ionization. Automatic compensation for changes in the solvent composition during gradient elution should be incorporated. A liquid nitrogen trap is positioned in the exhaust line between the source block and the rotary pump in order to avoid contamination of the pump oil by solvent used in LC-MS. Obviously, minor instrumental differences with respect to vaporizer design, temperature control and source block design are present between the various commercial systems. Two types of thermospray vaporizers have been in use, i.e. the Vestec-type vaporizer where the temperature control is based on measuring temperatures both at the stem near the solvent entrance and at the tip, where the nebulization is complete, and the Finnigan-type vaporizer where a thermocouple is spot-welded close to the inlet side at approximately one-quarter of the heated length.

Figure 1 Schematic diagram of a thermospray interface and ion source.

Figure 2 Schematic representation of the thermospray vaporization process. Reprinted with permission from Vestal ML and Fergusson GJ (1985) *Analytical Chemistry* 57: 2373–2378, © 1985, American Chemical Society.

A schematic representation of the thermospray nebulization process is shown in **Figure 2**. Initially, in the first part of the vaporizer tube, the liquid is heated until, at a certain stage, the onset of vaporization takes place. The vaporization process will start at the heated capillary walls and results in tearing of the liquid: bubbles are formed within the liquid. Upon continuing vaporization, the stage of bubbles in the liquid transforms to liquid droplets in a vapour. The temperature measured at the vaporizer tube wall over the length of the capillary is also shown in **Figure 2**. When complete solvent evaporation inside the tube would be achieved, a sharp increase of the capillary wall temperature would be observed, where the vapour is heated. However, optimum ionization conditions are achieved at nearly complete inside-tube vaporization. From this description of the nebulization process, it may be concluded that the contact time between the liquid and the analyte molecules dissolved in the liquid and the hot surface of the capillary is relatively short. This limits the extent of thermal decomposition of labile analytes.

Most thermospray interfaces have been fitted onto (triple) quadrupole mass analysers, although thermospray interfaces for magnetic sector instruments were commercially available as well.

Thermospray Ionization Modes

The thermospray interface can be used in various modes of ionization, depending on the settings of experimental parameters and the choice of the solvent composition. The thermospray nebulization process provides for a rapid and efficient means to partially evaporate the solvent mixtures introduced into the system by means of the production of small heated droplets. For clarity of the discussion, four ionization modes are distinguished here, i.e. two electron-initiated modes and two liquid-based ionization modes.

The two electron-initiated ionization modes are filament-on and discharge-on ionization. In these modes, the thermospray interface is used as a solvent introduction device, providing nebulization and soft transfer of analytes from the liquid to the gas phase. High-energy electrons are generated by means of a heated filament or at a corona discharge electrode. These electrons produce molecular ions of solvent molecules in the high-pressure (typically 1 kPa) source. In a series of ion-molecule reactions, the solvent molecular ions are converted to solvent-based reagent gas ions, i.e. protonated molecules and clusters, similar to the processes in a chemical ionization source. Protonated $[M + H]^+$ or deprotonated $[M - H]^-$ analyte molecules are produced in positive-ion and negative-ion mode, respectively, as a result of gas-phase proton-transfer reactions, while various other

even-electron ionic species (adducts such as the ammoniated molecule $[M + \text{NH}_4]^+$, $[M + \text{CH}_3\text{OH} + \text{H}]^+$, or $[M + \text{CH}_3\text{COO}]^-$) may be produced as well.

The two liquid-based ionization modes are based on ion evaporation processes, initially proposed by Iribarne and Thomson. The mechanism can be summarized as follows: During thermospray nebulization, a superheated mist carried in a supersonic vapour jet is generated. Nonvolatile molecules are preferentially retained in the droplets, which are charged due to the statistical random sampling of the buffer ions in solution. As a result of continuous solvent evaporation from the droplets and repeated droplet breakdown by Rayleigh instabilities, a high local field strength is generated allowing charged species to desorb or evaporate from the droplets. These charged species comprise analyte molecules, present as preformed ions in solution, and buffer-solvent cluster ions, that rapidly equilibrate with the vapour in the ion source. Ion-molecule reactions may occur between the ions and neutrals in the source. A schematic illustration of the thermospray ionization mechanism is provided in Figure 3.

The ion evaporation mechanism in thermospray ionization has been criticized, by, among others, Röllgen and co-workers, who propose an alternative model, i.e. the charge residue or soft desolvation model. According to this model, the preformed ion of the nonvolatile analyte molecule is kept in a droplet, which decreases in size due to continuous solvent evaporation and repetitive Rayleigh instabilities until the droplet has become so small that it can be considered as a solvated ion. The ionization is thus the result of soft desolvation of the preformed analyte ions. Interestingly, the discussion between these two mechanisms reappears in the discussion on electrospray ionization, although in a slightly different manner.

Irrespective of the exact mechanism, ion evaporation or soft desolvation, it is important to pursue the generation of preformed ions in solution, i.e. by adjusting pH, and to reduce the influence of competitive ions, i.e. to

keep the ionic strength of other ions as low as possible. Surprisingly, the latter is not a common practice in thermospray ionization. The most widely applied liquid-based thermospray ionization mode appears to perform best in the presence of rather high ($0.05\text{--}0.2\text{ mol L}^{-1}$) concentrations of ammonium acetate or formate. Under these conditions, the evaporation of solvated ammonium ions generally will be more effective than the ion evaporation of preformed analyte molecules, especially because the latter are present in significantly lower concentrations. As a result, gas-phase ion-molecule reactions between ion-evaporated ammonium ions and neutral analyte molecules will significantly contribute to the ionization yield in most thermospray applications. Therefore, two liquid-based ionization strategies are indicated and discriminated here, i.e. one based on ion evaporation of preformed analyte ions in solution (thermospray ion evaporation mode), and one based on ion evaporation of solvent buffer ions followed by gas-phase ion-molecule reactions with neutral analyte species, efficiently transferred to the gas phase by means of nebulization and subsequent droplet evaporation, to produce protonated or deprotonated analyte ions (thermospray buffer ionization mode).

It must be emphasized that the resulting ions from either mechanism are the same. Therefore, it appears difficult to discriminate between the various mechanisms, especially because a mixed ionization mode, where various processes contribute to the final mass spectrum, is most likely.

Although the ion evaporation mechanism is the most popular view on the thermospray ionization mechanism, the ionization characteristics under typical operating conditions, and for most analytes, are best understood in terms of chemical ionization. Although for particular compounds differences between the filament-on and discharge-on modes were observed, in general these two modes can be treated in the same way.

Figure 3 Schematic illustration of the liquid-based thermospray ionization modes. Reprinted with permission from Vestal ML (1983) *International Journal of Mass Spectrometry and Ion Physics* 46: 193–196, © 1983, Elsevier Science.

In both modes, analyte ionization is due to a gas-phase ion–molecule reaction between analyte molecules and reagent gas ions. The latter are generated from the solvent vapour in the high-pressure ion source by means of energetic electrons, basically similar to the generation of any other reagent gas in a source for chemical ionization.

The reagent gas composition is determined by the composition of the solvent mixture or mobile phase introduced. The reagent gas mass spectrum is often quite complex, containing several solvent cluster ions, but is generally dominated by the ionic species derived from the component in the solvent mixture with the highest proton affinity (in positive-ion mode) or the lowest gas-phase acidity (in negative-ion mode), although concentration effects may play a role as well. Proton affinities (gas-phase basicity) of common mobile-phase constituents are given in **Table 2**, while gas-phase acidities are given in **Table 3**. From these data it can be concluded that in positive-ion mode the reagent gas due to a 50:50 water-methanol mixture is dominated by methanol-related ions, e.g. at m/z 33, 65 and 97 due to $[(CH_3OH)_n + H]^+$ with $n = 1, 2$ and 3, respectively. After addition of ammonium acetate to this solvent mixture, the most abundant reagent gas ions are ammonium related ions, e.g. at m/z 50, 78 and 110, due to

$[NH_4 \cdot CH_3OH]^+$, $[NH_4 \cdot CH_3COOH]^+$ and $[NH_4 \cdot CH_3OH \cdot CH_3COOH]^+$, respectively.

In positive-ion mode, analyte ionization to a protonated molecule may take place when the proton affinity of the analyte exceeds that of the reagent gas. Typical values of proton affinities for a number of monofunctional analytes are given in **Table 2**. For multifunctional analytes, the proton affinity is roughly determined by the proton affinity of the functional group with the highest proton affinity. From **Table 2**, it may be concluded that the solvent mixture without ammonium acetate has a wider applicability range. In practice, however, ammonium acetate is added to the mobile phase in over 80% of the applications with filament-on or discharge-on modes, partly because of the need to apply a buffer in order to achieve reproducible retention times in LC. Next to protonated molecules $[M + H]^+$ a variety of adduct ions may be generated. When the proton affinity of the analyte is within $\sim 30 \text{ kJ mol}^{-1}$ of that of the reagent gas, adduct ions, e.g. $[M + NH_4]^+$, may be found. Furthermore, a series of solvent cluster ions may be observed, generally with low intensity. Maeder elaborately studied the various ions observed in thermospray ionizations and proposed a general formula:

where M is the analyte molecule, A is the attached cation, e.g. the proton or ammonium ion, B is an attached solvent molecule, C is an eliminated molecule, e.g. water, and x and y take integer values of 0, 1, 2, The presence of adduct ions next to the protonated molecule may be useful to ascertain the molecular-mass determination.

In the negative-ion mode, analyte ionization to a deprotonated molecule $[M - H]^-$ may take place when the gas phase acidity of the reagent gas exceeds that of the analyte, while similarly adduct ions may be observed as well. Typical values of the gas-phase acidity for a number of monofunctional analytes are given in **Table 3**.

These same ionization rules can be applied to predict the ionization behaviour of compounds in thermospray buffer ionization, where the analyte ionization is primarily dependent on the gas-phase ion–molecule reaction with ion-evaporated buffer ions, i.e. ammonium and acetate or formate.

In all instances, soft ionization of the analyte molecules is achieved, i.e. generally little fragmentation is observed. Obviously, there are a number of parameters other than the solvent composition that determine the ionization behaviour, e.g. analyte properties, temperatures, pressure. The temperature plays an important role because of its many influences on the ionization behaviour, but also on the production of ions due to thermal decomposition of thermolabile analytes. In most cases, thermal decomposition of analytes already takes place in the vaporizer tube, and the

Table 2 Proton affinities of some common mobile-phase constituents (PA_A) and of typical compound classes with one functional group (PA_M) in kJ mol^{-1}

Trifluoroacetic acid	1323	Benzoic acid	1420

mixture of analyte-related molecules is subsequently ionized. The mass spectrum appears to show fragmentation, although some of the fragment ions observed cannot be explained from a mass spectrometric point-of-view, but rather are due to hydrolysis and subsequent ionization of the hydrolysis product.

The general lack of fragmentation under thermospray conditions has led to the more extensive application of MS/MS instrumentation as well as to research into the possibilities of collision-induced dissociation of ions in the ion source by means of high voltages on the repeller electrode. The latter showed nice perspectives in fundamental studies, with mass spectra quite similar to those observed in MS/MS but they proved to lead to a signal reduction that was too large for successful use in real-life applications.

Operation and Optimization

The thermospray interface for LC-MS is generally considered as a difficult interface. This is due to the fact that for a proper operation the careful optimization of a variety of mostly interrelated experimental parameters is required.

The performance of the interface is to a large extent determined by the quality of the spray, which in turn depends on the quality of the vaporizer, the solvent composition and the temperature control at the vaporizer. The temperature at the vaporizer depends on the type: with a Vestec-type vaporizer the stem and tip temperature are typically set at $\sim 120^{\circ}\text{C}$ and 220°C , respectively, while the vaporizer temperature of a Finnigan-type vaporizer is typically set at $\sim 100^{\circ}\text{C}$.

Because the thermospray interface contains a dedicated ion source block, tuning and calibration of the source and analyser parameters is obligatory. Calibration and tuning cannot be performed with common calibrants like perfluorokerosene. Diluted solutions of polyethylene glycols are used in most cases, although a tuning and calibration based on clusters of ammonium acetate, ammonium trifluoroacetate and even simply water was proposed and used as well.

After tuning and calibration, the proper functioning of the interface can further be investigated by the injection of a number of standard compounds, e.g. adenosine and tertiary amines, as well as the compound(s) of interest. Subsequently, the system can be optimized to achieve the highest response or the best signal-to-noise ratio. Parameters to be studied are: the ammonium acetate concentration, the concentrations of the organic modifier and possible other mobile phase additives, the flow-rate, the optimum compound-dependent vaporizer temperature, the source block temperature, the repeller potential, as well as the ionization mode. A lower flow-rate generally

requires a lower vaporizer temperature, as does a higher content of the organic modifier. However, at a modifier content exceeding 40%, the thermospray buffer ionization mode is generally ineffective. Although the vaporizer temperature should be set in such a way that $\sim 95\%$ solvent vaporization inside the vaporizer is achieved, which in principle is primarily dependent on the flow-rate and the solvent composition, fine-tuning of the vaporizer temperature for a particular application may provide significant improvement of the performance. The analyte-related optimum of the vaporizer temperature may be sharp.

Applications

Thermospray ionization was especially applied between 1987 and 1992 in combination with LC-MS for a wide variety of compound classes, e.g. pesticides and herbicides, drugs and metabolites, alkaloids, glycosides and several other natural products, as well as peptides. A typical thermospray mass spectrum is given in **Figure 4**.

There are many studies available concerning the characterization of interface and ionization performance for the thermospray LC-MS analysis of pesticides, herbicides and insecticides, the improvement of detection limits and information content of the mass spectra. Compound classes most frequently studied are the carbamates, organophosphorous pesticides, triazine and phenylurea herbicides, chlorinated phenoxy acetic acids, and sulphonylureas.

Analytical strategies for the analysis of pesticides and herbicides in environmental samples, e.g. surface and tap water, are based on combined solid-phase extraction (SPE), LC separation and subsequent thermospray MS detection, often in a completely automated online system. Specific strategies have been developed for multi-residue screening as well as quantitative determination of pesticides and herbicides from specific compound classes. More recently, there is a growing interest in the determination and identification of pesticide and herbicide degradation products.

Environmental applications of LC-MS, not only pesticides and herbicides, but dyes, shellfish toxins, surfactants, organotin and other environmental contamination have been reviewed in a multi-authored book, edited by Barceló.

Thermospray LC-MS has also found frequent application in the qualitative and quantitative analysis of drugs and their metabolites in biological fluids, like plasma and urine, and tissue extracts.

In the drug development area, thermospray ionization has found application in open-access approaches, as the technique allows the rapid determination of the molecular mass of a synthesized product without the need to

Figure 4 Negative-ion thermospray mass spectrum of the disulfonated azo dye. Direct Red 81 (mobile phase contains 10 mmol L⁻¹ ammonium acetate).

optimize too many experimental variables. In this type of work, the thermospray interface is simply applied as an easy access to the MS.

Thermospray LC-MS, especially in combination with MS/MS, was successfully applied in the characterization of drug metabolites. Metabolite screening strategies based on precursor-ion or neutral-loss scan modes in MS/MS were also proposed for the detection of both Phase I and Phase II metabolites. For the Phase II metabolites, neutral loss scan with 176 or 80 Da losses for glucuronide and sulfate conjugates, respectively, were proposed. However, this approach is successful for only some Phase II metabolites, because it was found that the Phase II metabolites often undergo thermally induced ammoniolysis, resulting in mass spectra of the aglycones.

The thermospray interface was the first LC-MS system that allowed reliable quantitative bioanalysis for a wide variety of compounds. Numerous examples were published in the literature. An excellent example is the automated analysis of bambuterol. The automated system, described by Lindberg and co-workers, contained a series of feedback steps in order to assure the various components of the system were operating properly during overnight, unattended analysis and to avoid the loss of valuable sample material. The same approach was applied to the quantitative bioanalysis of cortisol and related steroid compounds. In order to enhance the response of cortisol in thermospray ionization, the compound was derivatized to the 21-acetate using acetic anhydride. This is a viable approach to slightly increase the proton affinity of an analyte to obtain improved ionization characteristics in thermospray buffer ionization.

Thermospray LC-MS was also frequently applied in the analysis of natural products, e.g. in extracts from

plants or cell cultures, of (modified) nucleosides, endogenous compounds such as prostaglandins, and some peptides. However, later it was demonstrated that alternative LC-MS strategies, e.g. based on electrospray ionization, were far more effective in the MS analysis of peptides.

Conclusion and Perspectives

For a number of years (1987–1992), thermospray LC-MS was the most frequently applied interface for LC-MS. It has demonstrated its applicability in both qualitative and quantitative analysis in various application areas. With the advent of the more robust LC-MS interfaces, based on atmospheric-pressure ionization, the use of thermospray interfacing and ionization rapidly decreased. The newer technology pointed out the limitations of the thermospray system, e.g. in the analysis of thermolabile compounds, ionic compounds, high molecular-mass compounds, as well as in robustness and user-friendliness. Therefore, thermospray as an ionization and interface technique for LC-MS is now history. Thermospray nebulization will continue to be used, e.g. in nebulization for ICP-MS.

Symbols

E	electric field strength of reflector
L_1, L_2	field- free path lengths (see Figure 2)
m	ion mass
q	ion charge
t	time; time of flight
v	ion velocity
V	electric potential
z	z coordinate; ionic charge
δ	variation in ion velocity

The time of flight (TOF) mass spectrometer is perhaps the simplest type of mass analyser, at least in principle. The kinetic energy of an ion of mass m is given by $mv^2/2$, so a measurement of its speed v by timing the flight of the ion over a given path determines the mass when the kinetic energy is known, or when the spectrometer has been suitably calibrated. Such an instrument was first proposed (in 1946) to take advantage of the improvements in timing circuits developed in the Second World War and in succeeding years it developed a reputation as a device with fast response but low resolution when used with an electron impact ion source. The Bendix Corporation manufactured a commercial TOF instrument that achieved considerable popularity, but later the technique fell into disuse when quadrupole mass filters became common. This situation has changed dramatically, and the field is now one of the most active areas in mass spectrometry. This has come about partly because of improvements in electronics, but mainly because of the development of new methods of ionization, particularly matrix-assisted laser desorption/ionization (MALDI). In addition, interest has shifted to the measurement of compounds of larger mass, for which TOF methods are especially well suited.

Ionization Methods

To define the ‘start signal’ for a TOF measurement, it is necessary to produce the ions as a series of short bursts. In some methods of ion production, this is achieved naturally, since the source itself is intrinsically pulsed. An early example of such a source is plasma desorption

mass spectrometry (PDMS). In this technique, ions are produced by bombardment of the sample with particles of MeV energies, usually fission fragments, and the pulses are formed by individual bombarding particles arriving at the target. More recently, much of the activity in the field has stemmed from the widespread use of MALDI, as remarked above. MALDI is also an intrinsically pulsed source, where the ions are produced by irradiation of a sample with a beam from a pulsed laser. The laser provides the start pulse, so the coupling to a TOF instrument is a natural one.

On the other hand, ions produced in a continuous beam must be formed into pulses by an appropriate device, so an additional complication is introduced. Examples are electron ionization, secondary-ion mass spectrometry (SIMS), and electrospray ionization (ESI). As mentioned above, the earliest commercial TOF instruments used electron-impact ionization, and the difficulty in producing short ion bursts with this method was mainly responsible for their limitations in mass resolution. However, new technology has enabled dramatically improved performance for continuous sources, particularly ESI, and TOF has gained widespread use with such sources as well.

A Simple Model

An idealized TOF instrument is illustrated in **Figure 1**. Here particle or laser bombardment desorbs an ion of charge $+q$ and mass m at time $t = 0$ from a sample deposited on the target, a plane conducting surface

Figure 1 Schematic diagram of a simple idealized time of flight mass spectrometer.

($z = 0$) that is held at potential $+V$. A parallel grid at $z = s$ is kept at ground potential so that there is a uniform electrostatic field directed along the z axis in the 'source region' between the target and the grid. If the ion starts out with zero velocity at the target, it is accelerated by the electric field and arrives at the grid with kinetic energy $\frac{1}{2}mv_z^2 = qV$ or velocity $v_z = \sqrt{(2qV)/m}$; its average velocity in the source region is half this value. The ion then passes through the ideal grid and travels with constant velocity through a drift region to the plane surface of a detector at $z = s + d$. Thus the total time of flight t is the sum of the time spent in the source region and the time spent in the drift region; i.e. $t = (2s + d)\sqrt{m/(2qV)}$. Measurement of the time of flight with a fast 'clock' determines the mass m , since the other parameters in the equation are known. Note that the time of flight is proportional to $\sqrt{m/q}$.

This geometry is close to that introduced by Macfarlane and Torgerson in their pioneering studies in PDMS in 1976, which marked a major step forward in the development of TOF techniques. As in the simple model, ions were ejected from an equipotential surface (by fission fragment bombardment in this case), so the spatial spreads that had limited the performance of earlier instruments were removed.

Features of TOF Measurements

The advantages of the technique in the ideal case can be seen from the simplified description above:

- The mass range of the analyser is unlimited, since the clock can simply be allowed to run until the ion of interest arrives at the detector. The only limits on the mass range are imposed by the ion source and the detector.
- Parallel detection of all the ions over the complete mass range is straightforward, because the mass is determined by the measured arrival time at the detector, and the arrival times of all ions can be recorded.
- Defining slits are unnecessary.
- Because of the previous points, sensitivity is high and the instrument has a fast time response.

In the past, the main disadvantage of TOF systems has been poor mass resolution, because of the difficulty of producing an ion beam consisting of very short bursts, and because of the inevitable departures from the ideal case. However, TOF resolution has been substantially increased recently by various technical improvements, as described below. Consequently, TOF instruments now often provide the optimum combination of resolution and sensitivity, particularly in cases where the whole mass spectrum is required. In contrast to the parallel detection capability of TOF instruments, most other

types of mass spectrometer operate as mass filters, in which the mass spectrum is obtained by scanning through the mass range, one mass at a time. Thus, in these instruments there is a reciprocal relationship between mass resolution and sensitivity; resolution must be sacrificed to obtain high sensitivity.

Compensation for Ion Energy Spreads with an Electrostatic Reflector

The most obvious defect of the simple model given above is its failure to take account of the initial energy that the ion possesses as it leaves the target. Variations in the initial energy may give rise to a considerable spread of times of flight, and thus to a deterioration in resolution. However, a modification to the instrument that alleviates this problem is the introduction of a reflector or ion mirror, as first proposed by Mamyrin (who called it a 'reflectron'). The simplest case is illustrated in **Figure 2**, where ions on a plane surface (the 'object plane') just outside the source region have a distribution of velocities. Ions travel freely from this surface until they enter a uniform retarding electrostatic field (an ion mirror). Like projectiles in the earth's gravitational field, ions follow

Figure 2 An illustration of the principle of ion mirror to compensate for velocity spreads. Two ion paths are shown for axial velocities $v_z = v_0$ and $v_z = v_0 + \delta$. The ion with higher velocity spends less time in the field-free region but more time in the mirror.

parabolic paths within the mirror and leave it with the ion velocity component parallel to the mirror axis (v_z) reversed. The ion then travels freely to the detector. For $L = L_1 + L_2$, the time spent in free flight is L/v_z , and the time spent in the mirror is $2mv_z/qE$, where E is the magnitude of the retarding electric field. If $v_z = v_0 + \delta$, we can expand as a function of (δ/v_0) to give a total time of flight:

$$t = \left[\frac{2mv_0}{qE} + \frac{L}{v_0} \right] + \left[\frac{\delta}{v_0} \right] \left[\frac{2mv_0}{qE} - \frac{L}{v_0} \right] + \dots \quad [1]$$

Setting $2mv_0/qE = L/v_0$, or $E = 2mv_0^2/qL$ removes the first-order term in δ/v_0 . Thus the reflector eliminates the effect of a velocity variation δ to first order. Under this condition, the total time of flight $t = 2L/v_0$, so the ion spends equal amounts of time in the mirror and in free flight. Higher-order terms can be removed by the use of more complicated electric fields, for example by the two-stage mirror described by Mamyrin, but any advantage in doing so is often lost because the resolution may deteriorate because of other effects, particularly in the acceleration region, which must be considered separately.

Space and Velocity Focusing in the Acceleration Region

As pointed out above, variations in ion velocity on the object plane can be corrected to a large extent by the use of a reflector. However, effects during ion production or acceleration may give not only a spread in velocity on this plane but also a spread in time. The latter effects are not corrected by the mirror.

Some of these phenomena were discussed in a classic paper of 1955 by Wiley and McLaren in connection with their TOF studies of ions produced by electron ionization, which in general may have both an initial spatial spread and an initial velocity spread. They considered an ion source with two stages of acceleration in series, each with a uniform longitudinal electric field. They pointed out first that ions with a pure spatial spread in the acceleration region are subject to 'space focusing'; that is, there is some plane beyond the grid that ions of the same mass will reach at approximately the same time. This is because ions initially close to the grid acquire less energy in the acceleration region than more distant ions and therefore are overtaken by the latter after travelling some distance determined by their original position and the accelerating electric fields. In the special case of a single uniform field, the focal plane is a short distance $D = 2s_0$ beyond the grid if the ions originate an average distance s_0 inside it. If a two-stage acceleration region is used, the position of the focal plane can be adjusted by changing the ratio of the electric fields in the two regions. When the ions arrive at this plane, they will have a velocity

spread because of the differing amounts of energy gained during acceleration, so the original spatial spread has been exchanged for a velocity spread.

This technique does not give perfect spatial focusing, even in the ideal case, but the usual limitation results from an initial velocity spread in addition to the spatial spread. The worst case involves two ions at the same z position but with velocities in opposite directions when the extraction pulse is applied. The ion in the negative z direction must first be turned around, and the two ions will arrive at the focal plane separated by this 'turn-around time'.

If the ions are produced in pulses (e.g. if the electron gun in an electron ionization source is pulsed), then some velocity compensation in the above situation is possible by the use of 'time-lag focusing', also proposed by Wiley and McLaren. In this technique, now usually called delayed extraction, a delay is introduced between ion production and the application of the accelerating fields, during which the ions drift freely. For simplicity, consider ions starting with zero spatial spread, i.e. with a pure velocity spread. When the accelerating field is applied, the ions will be separated in space according to their velocity. Those ions with higher initial v_z will be closer to the end of the acceleration region and will receive a smaller accelerating impulse. If the time delay and the amplitude of the accelerating voltage are adjusted properly, ions of the same mass will arrive at a focal plane at approximately the same time.

In the general case there may be both spatial and velocity spreads in the initial ion distribution, so some compromise is necessary to give optimum focusing. However, two currently popular ionization methods, ESI and MALDI, approximate the two limiting cases described above. Ions suitably injected from an ESI source have an appreciable spatial spread, but a very small velocity spread (see below). A pure velocity spread is approximated by the geometry normally used for MALDI, since the MALDI ions are ejected from an equipotential target by a very short laser pulse. In a simple linear TOF spectrometer, resolution can be optimized in both cases by using a two-stage acceleration region and setting the accelerating fields so that the focal plane coincides with the plane of the detector.

A Modern TOF Geometry

The best performance of TOF instruments is now achieved by a combination of an electrostatic reflector and the Wiley–McLaren focusing techniques, and this combination is the basis for most high-performance TOF systems.

By themselves, the Wiley–McLaren focusing methods are limited because the narrowest time distributions are

achieved for short flight paths, but good mass resolution requires long flight paths to provide time dispersion between ions of different masses. The electrostatic mirror provides energy focusing but does not compensate for time spreads in the source region, so by itself it also offers limited improvement. However, the two methods are highly effective when used in combination. The ions from the source are focused into a flat ion packet near the source and coincident with the object plane of the mirror (see **Figure 2**). The mirror then images the ion packet onto the detector, greatly increasing the time of flight and therefore the time dispersion between species, without appreciably increasing the time spread. The ions at the first focal plane have a considerable velocity spread as mentioned above, but the mirror compensates to first order for velocity spreads in its object plane.

TOF Measurements with a Continuous Beam

As remarked above, a continuous beam must be formed into pulses before it is introduced into the TOF spectrometer. This requirement is an extra complication that is not present if the beam is intrinsically pulsed. However, there are several cases in which mass analysis of ions produced in a continuous beam can benefit considerably from the features of TOF instruments. For example, electrospray ionization has been the most successful technique for producing ions from intact noncovalent complexes, but these ions are often formed with high mass-to-charge ratios, beyond the range of quadrupole mass filters; TOF imposes no limit on the mass-to-charge ratio (m/z) range. A second example involves coupling of separation techniques such as high-performance liquid chromatography with mass spectrometry. The sensitivity and fast time response of TOF instruments are well suited for such an application, but most separation techniques produce a continuous output. The same can be said of coupling TOF instruments with other types of mass spectrometer in order to perform MS/MS measurements as discussed below. For these reasons, there is clearly a need for an effective method for coupling continuous sources to TOF instruments.

A continuous beam can be injected into a TOF spectrometer in the longitudinal geometry of **Figure 1**, but only with very low efficiency. A more practical arrangement is illustrated in **Figure 3**; here a continuous beam of ions enters the TOF instrument perpendicular to its axis with low velocity and is injected into the flight path by the electrical pulses indicated in the figure. This technique takes advantage of the relative insensitivity of TOF measurements to spatial spreads in a plane perpendicular to the TOF axis. Such 'orthogonal injection' geometries were first introduced in the early 1960s, but

Figure 3 A schematic diagram of an orthogonal-injection TOF instrument with an electrospray ionization source. Collisional cooling is used in a quadrupole ion guide to produce a beam with a small energy spread, and a small cross section. The pressure in the ion guide is typically tens of millitorr; the main TOF chamber is under high vacuum, typically 10^{-7} torr. Ions are pulsed into the spectrometer at a repetition rate of several kilohertz; packets of ions for one mass are shown at several positions along the ion path.

acquired particular relevance when used with an electrospray source and an ion mirror by Dodonov. Limits on the injection efficiency and the resolution are set by the spatial and velocity spreads of the injected beam as described above. The properties of these instruments are therefore considerably improved if they are preceded by an ion guide running at relatively high pressure (up to ~ 10 Pa) to provide collisional translational cooling of the ions before they enter the TOF spectrometer. In this way, a beam is produced with a small energy spread, limited by thermal velocities, allowing effective spatial focusing as described above.

Daughter-Ion Measurements in TOF Spectrometers

The study of the products of ion breakup can often give useful information about the molecular structure of the

parent ion. In the simplest measurement of this type, a metastable parent ion may suffer unimolecular decay as it passes down the flight tube (so-called 'post-source decay'). The velocities of the daughter ions or neutrals can be determined from their times of flight, but such a measurement in a linear TOF spectrometer yields little information, since the *velocities* of the decay products are approximately the same as the velocity of the parent ion, as a result of conservation of momentum. Thus a daughter ion cannot be distinguished by its time of flight in a simple linear instrument from the parent or from other daughters.

On the other hand, the kinetic energy of the parent ion is divided among its decay products, so daughter ions will have *energies* determined by their masses. In contrast to the situation in a linear TOF spectrometer, the total time of flight in a reflecting instrument depends on the ion's energy as well as its velocity, because the ratio of ion energy to charge determines the distance the ion penetrates the mirror and thus the time spent there. The mirror does not correct for the velocity spreads of the daughter ions as well as it does for the parent (assuming that the electric field in the mirror is set to the value appropriate for the parent ion). However, for optimum resolution the problem can be minimized by examining the daughter-ion spectrum in segments, with the mirror field set to an appropriate value for each segment. Alternatively, a mirror with a nonlinear electric field can be used.

Usually there are a number of different parent ions extracted from the sample, each giving rise to a daughter-ion spectrum. It is therefore necessary to separate these in order to identify the particular parent ion giving rise to an observed decay. This is normally done by deflecting all ions except the desired one out of the flight path by some form of 'ion gate', and examining the decay products of the parent ions one by one.

The post-source decay technique suffers from some limitations, such as the limited selectivity obtainable on the parent ion, modest mass accuracy of the daughter ions (compared to the accuracy achieved for parent ions), and the frequently incomplete information obtained from the metastable decay spectrum. These factors have stimulated the development of various tandem instruments, as discussed below.

Tandem Instruments

Tandem mass spectrometers provide a more flexible means of studying molecular structure. Such devices combine a mass filter (MS1) to select the parent ion, a gas cell for collision-induced dissociation, and a second mass spectrometer (MS2) to analyse the daughter ions produced from breakup of the parent. A particularly suitable combination is a quadrupole mass filter (Q) as MS1, a

quadrupole ion guide (q) as the collision cell (excited by RF only), and a reflecting TOF instrument as MS2. MS/MS experiments are often limited by the amount of sample available, and by the time available to obtain a spectrum, so the sensitivity and rapid response of TOF offers a significant advantage over scanning instruments for MS2. Because of the parallel detection, the sensitivity can be maximized without reducing mass resolution. On the other hand, MS1 is simply used as a mass filter, so parallel detection offers no advantage, and a quadrupole mass filter is a good choice because it can be efficiently coupled to the collision cell. The QqTOF geometry thus offers an improved alternative to the popular triple-quadrupole instrument. Recently, TOF/TOF tandem MS instruments have also become popular, particularly with MALDI ion sources, for both MS only and MS/MS (fragment ion analysis modes).

Detection Methods

Detection in most types of mass spectrometer depends on measurement of the electrons or the secondary ions ejected from a surface by the impact of the ions of interest, usually after electron multiplication. A TOF detector must obviously have a fast time response. It must also have a large and flat active area, since the cross section of the ion beam at the detector is relatively large (usually several centimetres). Finally, to exploit the high mass range that TOF is capable of, the detector must be sensitive to ions with high m/z , which for a given energy have relatively low velocity.

The first two of the above demands are met effectively with microchannel plate (MCP) electron multipliers. These are flat arrays (of various dimensions) of micrometre-sized channels, each one acting as a very fast electron multiplier when a voltage gradient exists along it. Most high-resolution TOF instruments now use a microchannel plate for the first element of the detector.

The secondary emission coefficient decreases rapidly for decreasing velocity, and therefore for increasing m/z . For this reason, the ions are usually accelerated to relatively high energies before they are incident on the detector. Most MALDI/TOF instruments use 30 kV acceleration or more. Even so, for singly charged ions larger than about 50 kDa, the electron emission coefficient is considerably less than unity. Detection by electron emission still appears to be feasible in the high mass range because of the large number of ions desorbed in MALDI, although more efficient detection is possible by using a detector designed to take advantage of secondary ion emission at the cost of some loss of resolution.

The problem of detecting high masses does not occur when an ESI source is used, because it produces ions with much higher charge states, and therefore much higher

energy (and lower m/z) for the same molecular mass. Intact molecular ions from brome mosaic virus with mass larger than 4.6 MDa ($m/z \sim 25\,000$) have been observed by ESI/TOF using only 5 kV acceleration.

Tritium NMR, Applications

John R Jones, University of Surrey, Guildford, UK

© 2010 Elsevier Ltd. All rights reserved.

This article is reproduced from the previous edition, volume 3, pp 2366–2369, © 1999, Elsevier Ltd., with an updated Further Reading section supplied by the Editor.

It is undoubtedly true that if tritium were not radioactive it would be one of the most widely used of all NMR nuclei. Its favourable properties – an isotope of hydrogen, one of the most important of all the elements, with a nuclear spin $I = \frac{1}{2}$ and the most sensitive of all NMR nuclei – counts but little with those who quake at the mention of the word ‘radioactivity’, let alone think of spinning radioactive samples. However, there are those, increasing in number, who believe that tritium is the most favoured of all the nuclei, combining the advantages of favourable radioactive properties weak β^- emitter ($E_{\text{avg}} \sim 6 \text{ keV}$), convenient half-life (12.3 years), ready detection by liquid scintillation counting with good efficiencies (typically $> 50\%$) with these positive NMR characteristics. Furthermore the technology for synthesizing and handling tritiated compounds has been in place for many years whilst the development of spectrometers operating at ever increasing fields means that less tritium is required for NMR detection. In addition there is virtually no natural abundance tritium concentration, unlike the situation that exists for stable isotopes, so that the dynamic range is enormous. It is this factor above all others that will lead to an expansion in the use of tritium and tritium NMR spectroscopy in the life sciences. Recent publications show that such possibilities are being increasingly appreciated. The whole subject of tritium NMR spectroscopy was reviewed in 2005, see Further Reading.

Properties of the Nucleus

As well as having a nuclear spin $I = \frac{1}{2}$ tritium has a high nuclear magnetic moment which is responsible for the magnetogyric constant being larger than for any other nucleus, as also is its sensitivity to NMR detection, 21% higher than that for ^1H . At 11.7 T, at which field the ^1H NMR frequency is 500 MHz, the ^3H NMR frequency will be 533.3 MHz.

Sample Preparation and Spectrum Measurement

Before embarking on any ^3H NMR work the personnel must become designated radiation workers, have the appropriate radiochemical facilities and become familiar with tritiation procedures. In this respect it is frequently useful for initial training to be given in appropriate

deuteration studies although the corresponding tritium work will usually be carried out on a much smaller scale and the purification procedures will depend greatly on appropriate radio-chromatographic methods, as distinct from chromatographic methods. With appropriate rules and regulations in place a radiochemical laboratory need not be any more hazardous than an ordinary chemistry laboratory, particularly if the rule ‘that only the minimum amount of radioactivity consistent with the requirements of the project’ is used.

There are two separate units of radioactivity in use, the first being the curie (Ci) which is defined as an activity of 3.7×10^{10} disintegrations per second. This is a large unit, hence the frequent use of smaller subunits, the millicurie (10^{-3} Ci) and the microcurie (10^{-6} Ci). The second, and more recently introduced unit, is the becquerel (Bq). At one disintegration per second this is an extremely small amount of radioactivity. The conversions are

$$1 \text{ Bq} = 2.703 \times 10^{-11} \text{ Ci} \quad (27.03 \text{ p Ci}),$$

$$1 \text{ Ci} = 3.7 \times 10^{10} \text{ Bq} \text{ or } 37 \text{ GBq}$$

Although there are a large number of methods available for preparing tritiated compounds, the most widely used stem from the following categories:

- catalytic hydrogenation of an unsaturated precursor using $^3\text{H}_2$ gas;
- catalytic halogen–tritium replacement reactions;
- hydrogen isotope exchange reactions catalysed by acids, bases or metals;
- reductions using reagents such as sodium borotritide;
- methylation reactions using reagents such as tritiated methyl iodide.

Microwaves have been used to greatly accelerate the rates of many of these reactions whilst the development of microwave-enhanced solid state tritiation procedures offers considerable potential.

For ^3H NMR analysis 1–10 mCi of material dissolved in ~ 50 – $100 \mu\text{l}$ of a deuterated solvent is usually sufficient to obtain a spectrum of good signal-to-noise in a matter of 1–10 h, depending on whether the radioactivity is located at one site (a specifically labelled compound) or in several positions (a general labelled compound) – this assumes a spectrometer operating at 300 MHz for ^1H and 320 MHz for ^3H . For reasons of safety the radioactive

samples are placed in narrow cylindrical tubes, sealed at the top, which themselves are placed in standard NMR tubes – this double containment procedure, initially introduced when much higher levels of radioactivity were required, provides a measure of safety as well as reassurance. Experience shows that ^3H NMR spectra are of two kinds. Firstly there are those in which the specific activity of the compound is less than $\sim 1 \text{ Ci mmol}^{-1}$ so that ^3H – ^3H couplings are absent and the ^3H NMR (^1H decoupled) spectra consist of a series of single lines, which on integration give the relative incorporation of ^3H at each site. Nuclear Overhauser effects (NOEs) are small and differential effects even smaller so that there is no need to obtain NOE-suppressed spectra. It should also be mentioned that there is no need to synthesize a tritiated organic standard – all the ^3H chemical shifts are obtained via the ^1H chemical shifts and the Larmor frequency ratio.

For compounds at high specific activity, e.g. prepared by the addition of $^3\text{H}_2$ gas across the unsaturated group of a precursor, there will be tritium–tritium couplings, the magnitude of which are similar to those of hydrogen, i.e. $J(^1\text{H}$ – $^3\text{H}) = J(^1\text{H}$ – $^1\text{H}) \times 1.066$. Small isotope effects are present but these do not complicate the interpretation of the spectra; on the contrary they can aid the analysis of the relative proportions of isotopomers present, e.g. $\text{RC } ^3\text{H}_3$, $\text{RC } ^1\text{H}^3\text{H}_2$ and $\text{RC } ^1\text{H}_2^3\text{H}$. Tritium couplings to boron, deuterium, carbon, fluorine and phosphorus are also in agreement with theory.

Applications of Tritium NMR

New Tritium Labelling Reagents

The development of ^3H NMR spectroscopy has made possible many new applications and in the process has stimulated research into the development of new labelling reagents and hence new/improved labelling procedures. One such area is that of tritide reagents. Essentially carrier-free LiB^3H_4 can now be obtained via the two-step sequence:

Similarly, carrier-free sodium triethylborotritide, a useful reagent for the stereo- and regiospecific reduction of carbonyl-containing compounds, can be synthesized in the following manner:

Tri-*n*-butyltin and lithium tri-*s*-butylborotritide are other useful reagents. Increasingly sophisticated tritium

labelling technology is being developed as an alternative to the more traditional hydrogenation and catalytic dehalogenation reactions. The procedures will find wide application in the tritiation of molecules of biological importance. Thus *N*-tritioacetoxyphthalimide, a high specific activity tritioacetylating reagent, has been used to label a number of acetylenes, ketones and alcohols whilst radical-induced tritiooxygenation reactions can lead to the synthesis of important heterocyclic compounds.

New More Selective Tritiation Procedures

Hydrogen isotope exchange reactions are widely used not only to study reaction mechanisms but also for labelling compounds with either deuterium or tritium. The reactions may be catalysed by acids or bases under both homogeneous or heterogeneous conditions and frequently lead to generally labelled compounds. The same is true for transition metals. Considerable effort has been directed at developing more selective procedures – homogeneous rhodium trichloride has been shown to be very effective in introducing both deuterium and tritium into the *ortho*-aromatic positions of a wide range of pharmaceutically important compounds.

The well-known iridium catalyst $[\text{Ir}(\text{COD})(\text{Cy}_3\text{P})(\text{Py})]\text{PF}_6$, where COD = 1,5-cyclooctadiene and Py = pyridine, demonstrates excellent regioselectivity in isotopic exchange reactions of acetanilides and other substituted aromatic substrates. ^3H NMR spectroscopy is invaluable in identifying the site(s) of tritium incorporation – there are many instances where the broad signals in the corresponding ^2H NMR spectra are much less informative.

Another iridium catalyst that exhibits good regioselectivity in hydrogen isotope exchange reactions is the complex $[\text{IrH}_2(\text{acetone})_2(\text{PPh}_3)_2]\text{BF}_4$. As in the previous studies the transient existence of a metallocyclic intermediate is indicated. Considerable interest has also been shown in the development of the high temperature solid state catalytic isotopic exchange (HSCIE) method developed by Myasoedev and colleagues. Although labelling is uniform in most instances, some regiocontrol can be exerted by careful temperature control.

Chiral Methyl, Stereochemistry and Biosynthesis

The analysis of stereochemical problems in both chemistry and biochemistry has benefited greatly from the use of compounds that contain a methyl group with one atom each of ^1H , ^2H and ^3H . Such compounds exist as a pair of enantiomers, identified by *R* and *S*, and early work in this area will always be associated with the names of Arigoni and Cornforth. Recently a very efficient five-stage synthesis of chiral acetate has been reported (in which

the penultimate reaction uses supertritide) with an enantiomeric purity of 100%.

In the past the determination of whether an unknown sample contained an excess of an (*R*)- or (*S*)-configured chiral methyl group relied on using a reaction in which one hydrogen is removed to generate a methylene group in which tritium is now unevenly distributed between the two methylene hydrogens. The condensation of acetyl coenzyme A with glyoxylic acid catalysed by the enzyme malate synthase, which exhibits a primary kinetic isotope effect k_H/k_D of 3.8, was the chosen reaction. Analysis of the tritium distribution, together with a knowledge of k_H/k_D and the steric course of the reaction, yields the required information – the configuration of the original chiral methyl group and an estimate of the enantiomeric excess.

^3H NMR spectroscopy can provide the necessary information directly; whether ^3H has ^1H or ^2H as a neighbour can be determined directly from the ^1H - ^3H coupling and the ^2H isotope shift on the ^3H signal. The only problem with the ^3H NMR method is that it requires a few mCi of tritiated material, at least with current-day NMR spectrometers. With improvements in spectrometer design and the absence of 'natural abundance' tritium signals this may not always be the case. As it is, the method is direct, does not require any knowledge of the primary isotope effect and no chemical degradations are required.

There are many examples of enzymatic methyl-transfer reactions in biochemistry to which the chiral methyl/ ^3H NMR technology can be applied. One such example involves the important biological methyl donor *S*-adenosylmethionine. Combined with other studies the results show that the transfer of a methyl group to a variety of different nucleophiles all operate with inversion of methyl group configuration.

Substrate-Receptor Interactions

Most NMR studies in this area have used ^{13}C - or ^{15}N -labelled ligands, the synthesis of which is frequently more demanding than is the case for ^3H ligands. Furthermore, the sensitivity of both ^{13}C and ^{15}N nuclei to NMR detection is considerably less favourable than is the case for tritium. It is therefore somewhat surprising and at the same time disappointing that there are still relatively few

examples of protein-ligand interaction studies based on the use of ^3H -labelled ligands. In an early study ^3H NMR spectroscopy was used to monitor the anomeric binding specificity of α - and β -maltodextrins binding to a maltose-binding protein whilst in another study ^3H NMR spectroscopy was used to measure the dynamic properties of tosyl groups in specifically ^3H -labelled tosylchymotrypsin. Preliminary details of a ^3H NMR binding study of a tritium-labelled phospholipase A_2 inhibitor to bovine pancreatic PLA_2 suggest that the tritium atoms are located within the hydrophobic pocket of the protein. In a more extensive study a number of high specific activity tritiated folic acids and methotrexates have been prepared and their complexes with *Lactobacillus casei* dihydrofolate reductase (DHFR) investigated. The ^3H NMR results confirm the presence of three pH-dependent different conformational forms in the complex $\text{DHFR} \cdot \text{NADP}^+ \cdot \text{folate}$, whereas both the binary and ternary methotrexate complexes ($\text{DHFR} \cdot \text{MTX}$, $\text{DHFR} \cdot \text{NADP}^+ \cdot \text{MTX}$) were shown to exist as a single conformational state.

An interesting ^3H NMR study of the complex formed by $[4\text{-}^3\text{H}]$ benzenesulfonamide and human carbonic anhydrase 1 reveals details that are widely different from those obtained when using a fluorinated inhibitor, highlighting the dangers of using fluorine as a 'substitute' isotope for one of the hydrogen isotopes.

Macromolecules

The methods that have been developed for tritiating small organic molecules do not lend themselves very readily to the tritiation of large macromolecules such as proteins although there are a few examples where Myasoedov's HSCIE procedure proved successful. It is not surprising therefore that very little work has been reported on, for example, the ^3H NMR of proteins. The polymer area, however, has seen more activity, mainly because it has been much easier to tritiate such compounds – hydrogenation with $^3\text{H}_2$ gas of a suitable monomer followed by polymerization leads to a specifically tritiated product.

Many polymers are difficult to solubilize and the question has been asked several times whether in view of its good NMR characteristics it is possible to obtain satisfactory solid state spectra. The potential problems have been overcome partly by the development of zirconia rotors and partly by enclosing the tritium probe in a Perspex shield so that, in the event of an accident, radioactivity would be retained on a suitable filter. Magic-angle spinning at 17 kHz rotation provides spectra with line widths at half-height of the order of 120 Hz. This has been achieved without ^1H decoupling, this being a more difficult task than for solution studies. It is too early to say at this stage whether ^3H NMR spectroscopy

of solids will develop into as widely used a technique as ^{13}C NMR spectroscopy. The main factor will undoubtedly be how far improvements in NMR sensitivity can be extended.

Synopsis of Material to be Covered

Although NMR has been a valuable tool for scientists who must understand the structures, reactions, and dynamics of molecules, there have been two major advances in the past 30 years, which more than any other contributions, have kept this an exciting and rapidly evolving field. The first of these was the introduction of the Fourier transform NMR (FT-NMR) technique by Ernst and Anderson in 1966. This development helped to reduce problems associated with the biggest limitation of NMR – poor sensitivity. It also set the stage for a second important development. The dispersion of NMR signals and thus the complexity of molecules that can be studied is related to the magnetic field strength of the instrument. At a time when scientists were preparing ever more complicated structures, the incremental increases in the magnetic field strengths of commercially available instruments were growing smaller. However, the proposal by Jeener in 1971 and first demonstration by Muller et al. in 1975 of multidimensional NMR spectroscopy resulted in a quantum leap in the capabilities and the prospects for NMR. By dispersing the resonances in a second frequency dimension additional spectral dispersion could be achieved. The dispersion from a 2D experiment performed on a 1980 vintage 200 MHz spectrometer can match that obtained in the 1D spectrum from a modern 800 MHz spectrometer. In 2D spectroscopy, the spectral dispersion increases as the

square of the magnetic field strength. Furthermore, 2D experiments can have the unique characteristic of providing structural information based on the correlation of the frequencies at which peaks occur. This article deals with the background and practical aspects of obtaining 2D NMR data. There are quite a few variations of 2D NMR experiments in which properties such as retention time (in liquid chromatography-NMR (LC-NMR)), distances (imaging), or diffusion coefficients (diffusion ordered spectroscopy) are the variables along one or more axes in the spectra. However, discussions in this article will be restricted to experiments in which two frequencies, related to NMR parameters, are plotted along the two axes of the spectra. Other forms of 2D NMR are discussed in other parts of this work. Although this article can be read alone, it is useful to refer to other articles to learn the details of various techniques (e.g., weighting, zero filling, sampling rates, complex vs real Fourier transforms, linear prediction, sparse sampling, and other methods of fast 2D NMR) that are discussed in this article as they pertain to 2D NMR.

Fourier Transform NMR Spectroscopy

Figure 1(a) shows the time domain signal, called the free induction decay (FID), obtained by measuring the response of nuclear spins to a radio frequency (rf) pulse. The FID is the sum of many exponentially decaying cosine waves, one for each resolvable signal in the spectrum. In this time domain spectrum, a single frequency is observed; by measuring its period, the frequency can be determined. A typical FID will contain the sum of many oscillating signal components, making it impossible to identify individual frequency components by visual inspection of the time domain signal. By converting the time domain signal to a frequency domain

Figure 1 One-dimensional FT-NMR data: (a) time domain FID detected after an rf pulse and (b) frequency domain spectrum after Fourier transformation of the signal in (a).

signal using a mathematical process called Fourier transformation, a readily interpretable spectrum (**Figure 1(b)**) with peaks at discrete frequencies (one for each cosine wave in the original FID) can be obtained.

Each point in the time domain spectrum contains information about every frequency in the frequency domain spectrum. In a typical 1D spectrum up to 100k points are collected in the time domain; thus, information about each peak is measured 100k times. The laws of signal averaging tell us that the signal (S) from n measurements increases linearly ($n \times S$), but that the noise (N) from n measurements increases as $n^{1/2}$ ($n^{1/2} \times N$). Therefore, the signal-to-noise ratio (S/N) in the final spectrum improves as $n \times S / (n^{1/2} \times N) = n^{1/2} \times S/N$ as long as the signal is present throughout the FID. Consequently, the S/N in the final spectrum will be $(10^5)^{1/2} \cong 300$ -fold better than that obtained in a single scanned spectrum. This improvement is known as the Fellgett advantage. It is described here because it has some important consequences when n -dimensional experiments are performed. In practice, S/N gains, in 1D NMR are lower than those predicted by the Fellgett advantage, because the intensities of the signals decay exponentially during the signal acquisition period. However, in multi-dimensional NMR, short evolution and acquisition times have typically been used to minimize the size of the data sets and the time needed to collect the data. Consequently, very little signal decay occurs and S/N improvements are close to those expected from theory.

Fundamentals of 2D NMR

General Sequence for Collection of 2D NMR Spectra

Figure 2 contains a diagram of a 2D NMR pulse sequence called the NOESY (nuclear Overhauser enhancement spectroscopy) experiment. NMR spectroscopists have been very liberal in their methods for selecting acronyms to name their experiments. This pulse sequence contains the four basic elements that are common to 2D NMR experiments: preparation, evolution (t_1), mixing, and detection (t_2) times. The filled rectangular boxes represent 90° pulses, which are applied at the ^1H resonance

Figure 2 NOESY 2D NMR pulse sequence.

frequency in this experiment. In general, these pulses can be at a variety of flip angles and can be applied at a variety of frequencies depending on the requirements of the experiment and the information desired.

The preparation period is used to put the nuclear spins into the initial state required by the experiment being performed. In this particular sequence, the preparation period is a relaxation delay to allow the spins to return to their equilibrium Boltzmann distribution among the energy levels. In some sequences, the preparation period might also contain a coherence transfer step (e.g., by an INEPT-type polarization transfer pulse sequence) to move NMR signal components from one nucleus to another in preparation for the evolution period. The evolution period is used to encode frequency information in the indirectly detected (t_1) dimension. The mixing period is used to transfer magnetization from one nucleus (whose chemical shift information is encoded during t_1) to a second nucleus for detection during the acquisition period, t_2 .

The NOESY sequence contains a delay during the evolution period to encode ^1H chemical shifts; however, some pulse sequences contain 180° refocusing pulses to remove chemical shift modulation or coupling to a second nucleus (if the pulse is at the frequency of that second nucleus), or combinations of pulses to remove selected signals or coupling interactions.

The key to the success of 2D NMR is the collection of a series of FIDs, while progressively incrementing the value of t_1 . At the end of data collection a set of 100–1000 FIDs is obtained (the number of FIDs collected depends on the desired resolution and spectral window in the t_1 dimension) as shown in **Figure 3(a)**. The intensities of these FIDs are modulated based on the length of the t_1 period and the precession of the coherence during t_1 . If each of these FIDs is Fourier transformed (with respect to t_2), a series of spectra is obtained as shown in **Figure 3(b)**. Each spectrum contains signals that correspond to those found in the normal 1D spectrum of the detected nucleus. The intensity of a signal at a specific chemical shift varies from one spectrum to the next. Its intensity is modulated by the NMR interaction (J -coupling, chemical shift, multiple quantum coherence, etc.) that is in effect during t_1 and by the duration of the t_1 period. If one were to plot the intensities of the two peaks in **Figure 3(b)** as a function of t_1 , the curves in **Figure 3(c)** would be obtained. The modulation frequencies of these two curves are different because the detected signals in t_2 originate from different coherences that have different precession frequencies in t_1 .

The intensity variations in these curves are reminiscent of the 1D FIDs. The obvious (in 1971 it was not so obvious until Jeener pointed this out) thing to do with these signals is to transpose the data matrix, and at each frequency in f_2 , Fourier transform the data with respect to t_1 . The result is a spectrum with signal intensity

Figure 3 Schematic illustration of the process used to produce a 2D NMR spectrum.

Figure 4 COSY 2D NMR spectrum of ethanol: (a) stacked plot and (b) contour plot with contours plotted at intensities of 2^7 .

variations as a function of two frequencies as shown in **Figure 3(d)**. The frequencies plotted along the f_2 dimension correspond to those that are detected during t_2 (i.e., ^1H chemical shift and J -coupling if the sequence in **Figure 2** is used). The frequency plotted along the f_1 dimension corresponds to the precession properties of the coherences that are selected by the pulse sequence.

Presentation of 2D NMR Data

Figure 4(a) shows a stacked plot of a COSY (correlation spectroscopy) spectrum from ethanol. Detailed fine

structure is not resolved in this spectrum because of the greatly reduced digital resolution compared to that obtained in 1D NMR. This reduced digital resolution is not very detrimental, and is necessary to keep the 2D data files to a manageable size (vide infra).

The stacked plot (**Figure 4(a)**) is not the most desirable way to present the data because it involves a lot of plotting time and background peaks are often hidden by those in the foreground. The preferred method of presenting 2D data is in the form of contour maps, as shown in **Figure 4(b)**. For those unfamiliar with generation of contour maps, planes are set at a range of intensity values

(usually at levels x^n , where x is a user selectable number and $n = 0, 1, 2, 3, \dots$) above a user-determined threshold in the spectrum. The contour map is generated by plotting the intersections of the peaks with these planes. The more intense peaks will intersect a larger number of planes; therefore, peaks in **Figure 4(b)** that are defined by a larger number of contours are more intense than those defined by a small number of contours. In this display mode, peaks are not obscured and the printout is generated fairly rapidly. Although it does take a significant amount of computer power to calculate a contour map, modern computers are capable of doing so in much less time than it takes to transmit the data to most plotters. Commercial software packages for manipulating NMR data permit the adjustment of the number and spacing of the contours so as to best display all the peaks in the spectrum. In cases where all the signal intensities are of the same order of magnitude, x can be small (between 1.1 and 1.4) so that a large number of contours accurately define the peak shapes. In cases where there is a considerable dynamic range of peak heights, x can be large (2–4) to prevent the generation of a large number of contours around intense peaks.

Classes of 2D NMR Experiments

Part of the power of 2D NMR comes from its ability to provide tremendous spectral dispersion; however, the structural information present from the correlation of frequencies is equally important. Organic chemists have been doing elegant syntheses for many decades. They chose a target molecule for preparation, and based on their knowledge of chemical reactions selected the

proper reagents from their stockroom to carry out the chemical transformations necessary to obtain the desired product. Since the development of multidimensional NMR similar possibilities exist for studying molecular structure, reactivity, and dynamics. The NMR spectroscopist first defines the nature of the information needed to solve a particular problem. It is then possible to go to the ‘NMR stockroom,’ and choose from a variety of ‘NMR reagents,’ which include pulses, delays, frequencies, rf phases, rf amplitudes, magnetic field gradients, and so on. Using the right combination of these reagents, a spectrum can be produced with selected signals containing the needed information, while removing other undesired signals that interfere with observation of the interesting signals or the interpretation of the data.

As an example, **Figure 5** shows a COSY pulse sequence (**Figure 5(a)**) and the 2D COSY spectrum of 3-heptanone with the 1D ^1H spectrum plotted across the top (**Figure 5(b)**). The 2D spectrum contains a series of peaks along the diagonal whose positions in f_1 and f_2 correspond to the positions of the peaks in the 1D spectrum. Off the diagonal, cross peaks exist, which correlate the frequencies of proton pairs that are coupled to each other. In COSY spectra, these correlations indicate protons that are on adjacent carbons (or nonequivalent protons on the same carbon). Separate sets of cross peaks are observed for the ethyl (A) and butyl (B, C, and D) fragments of the molecule. Because the protons on these two fragments are more than three bonds away from each other, there is no J -coupling between protons on the two different groups. Consequently, none of the resonances from protons on the butyl fragment contain correlations to the resonances of protons on the ethyl fragment.

Figure 5 (a) COSY pulse sequence and (b) COSY spectrum of 3-heptanone with its 1D ^1H spectrum plotted across the top.

In general, the NMR parameter plotted along the f_2 dimension is related to the signal detected during the t_2 time period. The NMR parameter plotted along the f_1 dimension is determined by the precession frequencies of the NMR coherences during the t_1 period. A specific sequence of pulses can be used to place the NMR coherence on selected nuclei (e.g., ^1H or ^{13}C) to encode their NMR properties during t_1 ; a second series of pulses and delays are then used to transfer that coherence to the detected nucleus based on an NMR interaction (e.g., by J -coupling, dipolar coupling, or internuclear relaxation). Cross peaks in the 2D NMR spectrum identify pairs of nuclei that share this interaction. Some common 2D NMR experiments are shown in **Table 1**, along with the NMR parameters plotted along the f_2 and f_1 dimensions, the interaction that produces the correlations, the structure information obtained from the spectrum, typical experiment times, and some comments.

The experiments can arbitrarily be classified into four groups: homonuclear chemical shift correlation, heteronuclear chemical shift correlation, J -resolved, and multiple quantum experiments. The first six experiments in **Table 1** are homonuclear chemical shift correlation experiments. In one subset of homonuclear chemical shift correlation experiments, COSY- and TOCSY-type experiments, the same chemical shifts (usually those of ^1H) are plotted along the f_1 and f_2 axes. The 2D spectrum contains peaks along a diagonal at the intersections of the chemical shifts of each nucleus. If there is J -coupling between two nuclei, then off-diagonal cross peaks connect the diagonal peaks to form a box as in the COSY spectrum of 3-heptanone described earlier. The TOCSY experiment can produce, in addition, cross peaks for all protons involved in an unbroken chain of spin couplings. A second subset of homonuclear chemical shift correlation experiments (NOESY and ROESY) has an appearance identical to that of COSY-type experiments, but with off-diagonal cross peaks indicating proximity of two nuclei in space (usually the nuclei must be within 5 Å to produce NOESY cross peaks).

The second group of experiments produces 2D spectra with the chemical shifts of different nuclei along the two axes (e.g., ^1H along the f_1 axis and ^{13}C along the f_2 axis). A single cross peak is observed for each coupling interaction in HETCOR, COLOC, HMQC, HSQC, and HMBC experiments. The latter three experiments are sometimes put in their own classification, and are called indirect detection experiments. HETCOR-type experiments, which involve detection of the ^{13}C signal during t_2 , were the first commonly used experiments to provide ^1H - ^{13}C correlations. Later, after the performance of NMR instruments improved, the more sensitive and more challenging ^1H - ^{13}C correlation experiments involving detection of the ^1H signal during t_2 became popular. In these experiments, the chemical shift of the X

nucleus (usually ^{13}C) is indirectly detected in the t_1 dimension. Perhaps, if HMQC type experiments were popular first, then HETCOR-type experiments would now be called indirect detection experiments. The HOESY experiment is the heteronuclear version of the NOESY experiment, and contains cross peaks between the resonances of dissimilar nuclei if there is an NOE interaction between those nuclei.

The third class of experiment is the J -resolved series of pulse sequences. These produce spectra with the peaks at the frequencies along f_2 corresponding to the resonances observed in the 1D spectrum of the detected nucleus. In homonuclear 2D J -spectroscopy, the peaks are dispersed into the f_1 dimension based on homonuclear J -coupling. In heteronuclear 2D J -spectroscopy, the peaks are dispersed into the f_1 dimension based on heteronuclear J -coupling (e.g., detection of ^{13}C in f_2 and at the shift of each ^{13}C a multiplet, resulting from all of the resolved J_{CH} -couplings, is observed in f_1).

The fourth class of experiments involves multiple quantum spectroscopy such as 2D INADEQUATE. In these experiments, homonuclear shifts (such as those of ^{13}C) are plotted along the f_2 dimension. If two or more nuclei are J -coupled to each other, then they can be made to share a common multiple quantum precession frequency during the t_1 period. In the 2D INADEQUATE experiment if C_A and C_B are coupled to each other, then the signals from each of these components will precess at a common double quantum frequency ($\nu_A + \nu_B$) in the f_1 dimension.

Usually, two or more experiments are run, where the correlations in each experiment provide a set of structure fragments. The combined fragments can then be fitted together like the pieces of a puzzle, and in most instances, the right combination of multidimensional experiments can provide complete information about the structure of an unknown molecule.

As an example, if HSQC and HMBC spectra were obtained from *p*-nitrotoluene, the HSQC spectrum would provide C-H connectivities illustrated by the highlighted bonds in structure 1; HMBC would provide information that relates the ^1H shifts with ^{13}C shifts of atoms two and three bonds away. Some of these correlations are illustrated on structure 2. The combined information from the two experiments provides a complete structure of the molecule. Although a complete description of these experiments is beyond the scope of this article, some comments on experimental characteristics are worth noting. Experiments that involve ^1H detection are generally much more sensitive than those that involve ^{13}C detection, largely due to the higher γ of ^1H . The use of ^1H detection necessarily involves the elimination of all ^1H NMR peaks of protons attached to ^{12}C , approximately 99% of the total intensity, and this is achieved by suitable pulse sequences (vide infra). Even though

Table 1 Some common 2D NMR experiments and related information

Experiment name	f_2	f_1	NMR interaction	Structure information	Time ^a /sample quantity	Comments
COSY	δ_H	δ_H	$^2J_{HH}$ and $^3J_{HH}$	H-C-H and H-C-C-H	15 min/1 mg	Easy
DQ-COSY	δ_H	δ_H	$^2J_{HH}$ and $^3J_{HH}$	H-C-H and H-C-C-H	15 min/1 mg	Double quantum filtered COSY – same as COSY, but eliminates singlets that contain no information
Relayed COSY	δ_H	δ_H	$^2J_{HH}$ and $^3J_{HH}$	Hs in a spin system	15 min/1 mg	Easy
TOCSY	δ_H	δ_H	$^2J_{HH}$ and $^3J_{HH}$	Hs in a spin system	15 min/1 mg	Easy
NOESY	δ_H	δ_H	H-H dipole-dipole	r_{HH} conformation	4–12 h/5 mg	Usually 10–100 times weaker than COSY
ROESY	δ_H	δ_H	H-H dipole-dipole	r_{HH} conformation	4–12 h/5 mg	Usually 10–100 times weaker than COSY
HETCOR	δ_C	δ_H	$^1J_{CH}$	C-H	2–8 h/10 mg	^{13}C detected
Long-range HETCOR	δ_C	δ_H	$^2J_{CH}$ and $^3J_{CH}$	$\underline{C-C-H}$ and $\underline{C-C-C-H}$	2–8 h/10 mg	^{13}C detected
COLOC	δ_C	δ_H	$^2J_{CH}$ and $^3J_{CH}$	$\underline{C-C-H}$ and $\underline{C-C-C-H}$	2–8 h/10 mg	^{13}C detected
HMQC/HSQC	δ_C	δ_C	$^1J_{CH}$	C-H	1 h/5 mg	1H detected
IMPRESS-HSQC	δ_H	δ_C	$^1J_{CH}$ (spectral folding and editing possible)	C-H		1H detected
CRISIS-HSQC	δ_H	δ_C	$^1J_{CH}$	C-H		DPFGSE sequence incorporated for selective excitation
CRISIS2-HSQC	δ_H	δ_C	$^1J_{CH}$	C-H		Adiabatic 180° pulses on X channel
Ultra-SOFAST HMQC	δ_H	δ_C	$^1J_{CH}$	C-H		Adiabatic 180° pulses on both H and X channel
HMBC	δ_H	δ_C	$^2J_{CH}$ and $^3J_{CH}$	$\underline{C-C-H}$ and $\underline{C-C-C-H}$	1–4 h/5 mg	Single scan collection of entire 2D spectrum
CIGAR-HMBC	δ_H	δ_C	$^2J_{CH}$ and $^3J_{CH}$	$\underline{C-C-H}$ and $\underline{C-C-C-H}$	1–4 h/5 mg	1H detected
2J, 3J-HMBC	δ_H	δ_C	$^2J_{CH}$ and $^3J_{CH}$	$\underline{C-C-H}$ and $\underline{C-C-C-H}$	1–4 h/5 mg	Compensates for range of J couplings
H2BC	δ_H	δ_C	$^1J_{CH}$ and $^3J_{HH}$	$\underline{H-C-C-H}$	1–4 h/5 mg	Simultaneous detection of C-C-H and C-C-H couplings
HOESY	δ_C	δ_H	C-H dipole-dipole	r_{CH}	12 h/50 mg	Selective detection of two-bond C-H
Homonuclear 2D-J	δ_H	J_{HH}	J_{HH} scalar coupling	Conformation	20 min/1 mg	Difficult
Heteronuclear 2D-J	δ_C	J_{CH}	$^2J_{CH}$ and $^3J_{CH}$	Conformation and number of attached H	2–8 h/10 mg	Easy and fast
2D-INADEQUATE	δ_C	$\delta_C + \delta_C$	$^1J_{CC}$	$^{13}C_a-^{13}C_b$	12–16 h/100 mg	Moderate
						$1/10^4$ molecules, extremely difficult

^aTypical experiment times for a molecule with MW = 500 and experiments performed on a 300–400 MHz spectrometer.

HETCOR and HSQC provide similar frequency correlations and identical structure information, the former involves ^{13}C detection and generally requires approximately 30 times more sample to produce a spectrum of the same quality.

Although many of the experiments use similar interactions to provide correlations, experiments that use smaller, long-range J -couplings, require longer delays (usually approximately $1/2J$) than experiments that use large one-bond J -coupling. During these longer delays, relaxation effects reduce the intensities of the signals that are finally detected during t_2 , especially for large molecules having short T_2 relaxation times. Consequently, experiments like HMBP produce spectra with poorer S/N than its counterpart, HSQC.

Although all the entries in the second and third columns of **Table 1** refer to ^1H and ^{13}C , other combinations of NMR-active nuclei can be used to perform most of these experiments. For example, the experiments in the first six rows of **Table 1** are ^1H – ^1H homonuclear correlation experiments. These experiments will work just as well with ^{19}F – ^{19}F homonuclear correlation experiments if there are a number of mutually coupled fluorine atoms in the structure to be studied. Likewise, ^{15}N or ^{31}P , for example, could be substituted for ^{13}C in HSQC and HMBP experiments.

Experimental Aspects of 2D NMR

Acquisition Conditions

Instrument requirements

Most instruments that have been installed in the past 10 years are capable of performing all of the experiments shown in **Table 1**. Collection of 2D NMR spectra requires a stable instrument and a stable instrument environment. The exact requirements become more stringent at higher magnetic fields. For example, 600–800 MHz spectrometers generally require room temperature fluctuations less than $\pm 0.5^\circ\text{C}$, minimized air currents, and the magnet mounted on vibration isolation

pads. In some instances, it might be necessary to mount other mechanical equipment near the instrument (near is not used in an absolute sense since some buildings are more efficient at transmitting vibrations throughout the structure than others) on its own vibration isolation equipment. All of the experiments shown in **Table 1** can be performed on standard two-channel (i.e., ^1H and X channels) spectrometers.

Spectral resolution and data size

As mentioned earlier, a number of separate 1D FIDs are collected, each with a different value for t_1 . In 1D NMR spectroscopy, 50–100k data points are collected and Fourier transformed to provide a spectrum. The exact number of points depends on the spectral window, expected line widths, and the desired digital resolution (usually 0.1–0.5 Hz per point) in the 1D spectrum. If this digital resolution is maintained in both dimensions of a 2D experiment, the file size could grow to many gigabytes, and would be difficult to manipulate and store. Consequently, shortcuts are used to minimize the sizes of 2D data files. The first of these shortcuts is to minimize the spectral windows to include only those regions that are expected to contain peaks of interest. For example, in a COSY experiment that contains cross peaks between the resonances of coupled protons, the spectral window is narrowed to exclude singlets and solvent resonances. It is usually worthwhile to collect 1D spectra that correspond to the windows in the two dimensions before attempting to run the 2D experiment. In some cases, however, this may not be possible (e.g., if sample quantity is limited and the f_1 dimension is the ^{13}C chemical shift in an HSQC experiment).

A second shortcut is to drastically reduce the digital resolution in the 2D spectrum; typically the data is collected to provide 1–2 Hz per point digital resolution in the final spectrum. Typical t_2 (acquisition) times are 0.05–0.2 s, more than an order of magnitude smaller than those used in 1D NMR spectroscopy. The use of longer acquisition times has very little effect on data collection times. If a 1 s relaxation delay is used, increasing t_2 from 0.05 to 0.2 s results in 15% longer experiment time and provides a fourfold increase in digital resolution in f_2 (and a fourfold increase in the size of the data file). The same is not true in the t_1 dimension.

Typically, 100–500 separate FIDs are collected to produce the points in the t_1 dimension of a 2D spectrum. To obtain a fourfold increase in digital resolution in f_1 , four times as many FIDs must be collected, increasing the experiment time by more than fourfold (the t_1 period for the last FID will be significantly longer than for the first increment where $t_1 = 0$). If four transients are averaged for each of the 100 FIDs, the S/N in the resulting 2D spectrum would be comparable to that obtained in the corresponding 1D version of the experiment

(i.e., if only the first t_1 increment is collected) obtained by averaging 400 transients. However, in many cases the additional sensitivity achieved by collecting so many FIDs is not required and the 2D experiment is longer than is required for signal detection. To mitigate this problem various shortcuts have been devised to shorten 2D data accumulation times while improving spectral resolution (see sections below on Linear prediction and Sparse sampling of 2D NMR data).

Phase cycling for artifact suppression and coherence selection

There are a number of artifacts that can appear in 2D spectra, including peaks and ridges at the transmitter frequencies in f_1 and f_2 , and mirror images of the real peaks on the opposite side of the spectrum. These can arise from a number of sources, including the fact that some spins experience imperfect pulses. Even with a properly functioning instrument, nuclei whose resonances lie near the edge of the spectral window experience significantly different flip angles compared to those nuclei whose resonances lie near the transmitter, as a consequence of resonance offset effects. Additionally, even those nuclei whose resonances fall near the transmitter experience a gradation of flip angles depending on the position of the nuclei relative to the probe's transmitter coil (i.e., the nuclei in the portion of the sample near the middle of the tube experience a larger flip angle than nuclei in those portions of the sample near the top

and bottom of the tube). These artifacts are reduced by using either composite pulses or adiabatic pulses in place of simple 180° pulses (CRISIS versions of pulse sequences in **Table 1**). To further reduce artifacts, the phases of 180° pulses are shifted by 180° in alternate transients; and the phases of 90° pulses are usually incremented by 90° in a sequence of four transients. A sequence with both a 90° and a 180° pulse ideally would require averaging of eight transients to obtain a spectrum resulting from all permutations of the two phase cycles. In experiments with many pulses, the number of transients required to cycle the phases of all pulses becomes extremely large (spectra in which the number of transients per FID is 64–256 can be found in the early literature). Usually, artifacts from imperfections in one pulse are more prominent than those arising from imperfection in the other pulses in the sequence. In those cases, the phases that remove the most severe artifacts are cycled first. When setting up an experiment, it is necessary to know the number of transients needed to complete this minimum phase cycling, and to set up the experiment to collect an integral multiple of this number of transients.

Some of the 2D spectra result from cancellation experiments (i.e., coherence selection). The HMQC is an excellent example of experiments in this class. As described earlier, HMQC provides a 2D spectrum correlating the shifts of ^1H and directly bound ^{13}C nuclei. In the ^1H spectrum of 3-heptanone, the peaks that are normally observed are those from ^1H bound to ^{12}C (99% of the

Figure 6 Methylene regions between 2.2 and 2.5 ppm from the proton NMR spectra of 3-heptanone. (a) Normal ^1H spectrum, (b) $100\times$ vertical amplification of (a), (c and d) spectra obtained from collecting a single HMQC transient with phase cycling for odd and even transients, respectively, (e) spectrum in (d) minus spectrum in (c), and (f) single transient from HMQC spectrum obtained with PFG coherence selection.

Figure 7 (a) HMQC pulse sequence with phase cycling for coherence selection and (b) PFG-HMQC pulse sequence. In these diagrams, solid rectangles are 90° pulses, unfilled rectangles represent 180° pulses, and hashed rectangles represent field gradient pulses.

protons, **Figure 6(a)**); however, if the vertical scale of the spectrum is increased 100-fold, a set of satellite resonances from ^1H atoms bound to ^{13}C (1.1% of the signal, **Figure 6(b)**) are observed. To selectively detect the desired component from ^1H atoms bound to ^{13}C , the pulse sequence in **Figure 7(a)** is used. If the phase, Φ_1 , of the 90° ^{13}C pulse is applied along the $+x$ and $-x$ axes on odd and even transients, respectively, the sign of the undesired signals from ^1H bound to ^{12}C is unaffected; however, the phases of the desired signals from ^1H bound to ^{13}C are altered in odd and even transients. If the FIDs from odd transients (**Figure 6(c)**) are subtracted from those in even transients (**Figure 6(d)**) (by altering the phase of the receiver Φ_3), the undesired signals cancel and the desired signals add (**Figure 6(e)**). Detection of the desired signals requires observation of small differences between two large signals. Minor variations in the state of the instrument or its environment will result in imperfect cancellation (as evident by the large residual center signal in **Figure 6(e)**) and will produce large noise ridges that will obscure the cross peaks of interest. With a 64-cycle sequence, the residual center peak can be significantly reduced; however, once adequate S/N is achieved after a single transient, the experiment must still be run 64 times longer just to complete the phase cycling necessary to remove the artifacts. Furthermore, even when limited sample quantities result in the need to perform signal averaging, the residual signal intensity varies randomly from one pair of transients to the next, and adds like noise. The result is a ridge of noise along f_1 at the f_2 frequency of intense signals. This noise ridge, often called t_1 noise, limits the ability to detect weak cross peaks in the spectrum.

Pulsed field gradients for coherence selection

Pulsed field gradients (PFGs), also known as gradient enhanced spectroscopy (GES), can be used to achieve coherence selection and minimize the need for extensive phase cycling. In PFG spectroscopy a large z -gradient is introduced along the sample's vertical axis (magnitude approximately $0.1\text{--}0.5\text{ T m}^{-1}$ and duration approximately 1 ms); additional PFGs are introduced later in the sequence to selectively refocus the coherence components of interest and continue to destroy undesired coherence components. (In some rare cases, it is possible and advantageous to apply gradients along the three orthogonal axes (x , y and z) of the sample; however, few instruments are equipped with this capability.) The spectrum in **Figure 6(f)** was obtained by collecting a single HMQC transient with the aid of PFG coherence selection. The residual center peak from $^1\text{H}\text{--}^{12}\text{C}$ fragments is completely suppressed in one transient. The first obvious advantage of PFG spectroscopy is that excellent coherence selection is obtained in a single transient. Under these circumstances, the number of transients per FID is determined by sensitivity requirements and not the need to complete a phase cycle. Additionally, in cancellation experiments, the suppression level is less sensitive to instrument instabilities; and because the large undesired signal component never reaches the receiver, instrument gain settings can be optimized for detection of the weak signals of interest.

Quadrature detection in f_1 and f_2

When collecting 1D spectra on many modern instruments, two detection channels are present that independently measure the signals 90° out of phase with respect to one another (**Figure 8(a)**). Two FIDs, a real component and an imaginary component (which is 90° out of phase with respect to the real component of the signal), are saved; frequency information is obtained from the real component and phase information (i.e., whether the signal is to the left or right of the transmitter) is present in the imaginary component. A complex Fourier transformation produces a spectrum showing peaks with the proper relationship with respect to the transmitter, depending on the relative phase of the imaginary component in **Figure 8(a)**.

In 2D NMR, it is not possible to use a second detector in the f_1 dimension. There are alternatives that provide the equivalent of phase-sensitive detection in the f_1 dimension; the commonly used methods are the States' method, time-proportional phase increment (TPPI), and the combined States-TPPI method.

In the TPPI method a single data set with $2n$ t_1 increments is collected. In each successive t_1 increment the phase of the 90° pulse at the end of the t_1 period is incremented by 90° with respect to the phase of the corresponding pulse in the previous t_1 increment. (An

Figure 8 (a) Schematic illustration of real (r) and imaginary (i) components of the spectrum before FT. After FT the data can be represented in (b) phase-sensitive (PH) mode or (c) an absolute value (AV) mode and spectra can be calculated.

equivalent experiment can be performed in which the phases of the pulses before the t_1 period are shifted by 90° .) This is equivalent to changing the reference frame in f_1 so that the transmitter in the t_1 dimensions appears to be shifted to one edge of the spectrum. After performing a real Fourier transformation, all peaks will appear to be shifted to one side of the transmitter in f_1 . The main disadvantage of this technique is that phase distortions can appear for resonances in strongly coupled spin systems.

To obtain true quadrature detection, two sets of data with real and imaginary components in t_1 must be obtained. In the States method, two sets of 2D FIDs are collected and saved. Both data sets contain n FIDs ($2n$ total FIDs) and the t_1 delays in the corresponding FIDs in the two data sets are identical. Their only difference is that the second set of FIDs is collected with the phase of the 90° pulse immediately after the t_1 period shifted by 90° compared to the phase of the same pulse in the first set of FIDs. The first set of FIDs contains the frequency modulation information in t_1 and the second set of FIDs contains the phase information in t_1 , similar to quadrature detection in 1D NMR. After each of the FIDs in the two data sets are Fourier transformed, corresponding points from the two data sets are paired to form complex points in t_1 and a complex Fourier transformation is performed with respect to t_1 . This latter method provides data sets that are identical in size (and digital resolution) to those obtained from the TPPI method with equivalent digital resolution. The States method of phase-sensitive detection is usually preferred because artifacts are less problematic.

The third commonly used method of quadrature detection in t_1 combines the elements of the States and TPPI methods. Two sets of n FIDs are collected, 90° out of phase with respect to one another, but with the same t_1 values (as in the States method). Within each of these data sets the phase of the 90° read pulse at the end of t_1 is

incremented in 90° steps while incrementing t_1 (as in the TPPI method). With this technique, axial artifacts are shifted to the edges of the spectral window where they are less likely to interfere with cross peaks to be detected.

Kay et al. have devised a method called preservation of equivalent pathways (PEP) as data collected with PFG coherence selection and with States phase-sensitive detection components retain the P and N components of the signal in both 2D data set components. At the processing stage the real and imaginary components in t_1 are generated by the sum and difference of the collected data. In ideal cases, this method provides $2^{1/2}$ increase in S/N.

Establishing a steady state

Ideally, a relaxation delay of $3-5T_1$ should precede the cycle of pulses used to collect each transient. However, this would make experiments impractically long. Normally, 1–2 s relaxation delays are used, even though T_1 s might be 10 s or more. For larger molecules with shorter T_1 s, relaxation delays of 100–500 ms are used. Under these conditions, incomplete relaxation occurs. Consequently, the intensities of the signals in the first t_1 increment are artificially enhanced relative to the same signals in later increments. This means that the first point in t_1 is offset, leading to a large zero frequency offset in the baseline at slices corresponding to the resonance frequencies of all peaks in t_2 . To eradicate this problem, it is customary to perform 8–32 dummy scans, which are discarded, before collection of the data to be saved. During these dummy scans, ‘steady-state’ magnetization is established before data collection commences.

Linear prediction

Limited access to instrument time and the volume of data that must be collected means that shortcuts must always be taken, which adversely affect the appearance of the spectrum. Digital signal processing techniques can significantly enhance the appearance of a spectrum

without increasing data collection times. In some cases, when instrument time is at a very high premium, it might even be desirable to deliberately reduce the experiment time below the minimum needed for a reasonable spectrum knowing that processing techniques can be used to compensate for the missing data. Mathematically, it is possible to use the behavior of a function during time t , during which a measurement is made, to predict the behavior of the function if the measurement time had been extended by time t' (**Figure 9(a)**). As of this writing, in multidimensional NMR, linear prediction is one of the most used and most useful of these mathematical methods. Essentially, the oscillatory behavior of the signal intensity as a function of t_1 (at a specific f_2) is fit to the sum of a series of cosine waves. Since the number of peaks present at a single f_2 in a 2D spectrum is relatively small, the sum of a relatively small number of frequency components is sufficient to simulate the behavior of the FID in t_1 . The function can then be used to artificially synthesize values for the FID in t_1 as if a much larger number of t_1 increments had been collected. Usually the data are increased to two to four times the original size, and zero filling is applied to double the length of the data (e.g., if 2×256 t_1 increments were collected, linear

prediction would be used to forward extend the data to 2×1024 and zero filling could be used to further increase the size in t_1 to 2×2048). This permits improvements in resolution comparable to what would be achieved from an experiment that is up to four times longer than the actual experiment time.

Linear prediction can also be used to remove experimental artifacts from data. For example, the intensity of a single FID in the middle of a 2D experiment (**Figure 9(b)**) could be distorted if the field were perturbed for some reason. If steady-state pulses were not applied at the beginning of the experiment, the first few points in t_1 might be more intense than they should be (**Figure 9(c)**). In the former case, with linear prediction, the behavior of the FID on either side of the distorted point could be used to approximate the correct value of the distorted point. In the latter case, if the first two points are distorted, the behavior of the function for points 3–10 could be used to back predict the proper value of the points in the beginning of the FID.

Sparse sampling of 2D NMR data

As mentioned earlier, usually the limiting factor in collecting 2D data is not S/N; rather, it is the need to sample sufficient data points in the t_1 dimension to provide sufficient digital resolution. In most cases, long after sufficient signal is obtained, signal averaging is continued to provide sufficient digital resolution in the indirectly detected dimension. In simple 2D experiments, the experiment time increases approximately linearly as the digital resolution (number of t_1 increments) in the t_1 dimension is increased. Simultaneously, as the digital resolution increases so does the S/N also, as each point sampled in t_1 contributes to the S/N in the entire spectrum. The above-mentioned Fellgett advantage also applies to the indirectly detected dimension. If n FIDs are collected, a factor of $n^{1/2}$ increase in S/N can be expected compared to the 1D spectrum with averaging of the same number of transients. In most cases, limited availability of spectrometer time places a limit on the digital resolution in the t_1 dimension. The sampled data are schematically illustrated by the subset of sampled points in the lower left corner of **Figure 10(a)**. To improve digital resolution and minimize truncation artifacts in spectra with good S/N, linear prediction is used to fill in the data set with additional calculated data (gray data points in the central part of **Figure 10(a)**) before Fourier transformation to produce the final spectrum.

Recently, a number of other data sampling/processing methods have been proposed to contend with this sampling problem. These include selective excitation of subregions in the f_1 domain – analytical methods such as Hadamard techniques and application of numerical methods such as the filter diagonalization method (FDM) and maximum entropy methods (MEM). All

Figure 9 (a) Time domain NMR signal (FID) detected (full line), and calculated (dashed line) using linear prediction. (b) An FID from the middle of a 2D experiment with a single distorted data point (c) An FID with distorted signal intensity at the beginning.

Figure 10 Methods of dealing with sparse sampling of 2D NMR data sets: (a) small number of FIDs are collected and after $FT(t_2)$ linear prediction is used to calculate the gray points before $FT(t_1)$; (b) selective excitation at the few known peak positions in f_1 , and $FT(t_2)$, produces a 2D spectrum with information only at the two selective excitation frequencies in f_1 – no data is present between these frequencies; (c) Hadamard method of 2D NMR in which all peaks in f_1 are excited simultaneously, but with shaped pulses that alter the phases (+/-) of the peaks from one trace to another – the final spectrum is produced by taking linear combinations for the raw data based on the Hadamard mask; (d) sparse sampling of the FIDs in t_1 followed by MEM fitting of the data to produce the final high-resolution spectrum; and (e) FDM method of 2D NMR where only a few t_1 increments are sampled, followed by numerical transformation of the data from $S(t_1, t_2)$ into $S(f_1, f_2)$; sampling of many points in t_2 contributes to the information about peak positions in f_1 .

these techniques make use of sparse sampling schemes, followed by mathematical reconstruction of the n D NMR spectrum.

Selective excitation

If only a few (n) peaks are present in the f_1 dimension, selective excitation of each spectral region is performed and correlations to that region can be observed. After Fourier transformation with respect to t_2 , n separate selective 1D spectra are obtained, where correlations to the excited resonance are observed in the n respective regions. The concept of using n selective 1D spectra to replace the full 2D spectrum was first described two decades ago. The primary factor that has increased the

utility of these methods in recent years has been the development of flexible instrument hardware and software that enables the reproducible and accurate generation of rf pulse waveforms that can excite any arbitrary desired spectral window or combination of windows.

These methods work well when correlations to a relatively small number of peaks are desired. The drawback of this method comes when n (the number of spectral regions) becomes large. In these cases, many selective spectral windows must be collected, and the S/N values in each of these spectra are independent of one another. The experiment times can become quite long to signal average the necessary number of transients in each of the many desired spectral regions.

To circumvent these problems, in recent years the selective excitation methods have been adapted to Hadamard spectroscopic techniques. The Hadamard adaptation of selective experiments involves the use of rf waveforms such that in each FID a combination of selective pulses is simultaneously applied to all of the resonance positions in f_1 in such a manner as to excite (+) or invert (−) the peaks in n different regions; n different FIDs are collected containing linear combinations of the spectral components based on the Hadamard mask. Linear combinations of these n FIDs are calculated based on the Hadamard mask and these combined FIDs are Fourier transformed to produce n spectra each with one of the desired correlations. The appropriate linear combinations can be calculated on either the time or frequency domain signals in f_2 .

In the left part of **Figure 10(c)**, the simplest Hadamard data set, where $n=2$, is used as an example. Two FIDs are collected, where the excitation waveforms are such that the two regions have signal phases ++ in the first FID and +− in the second. Fourier transformation with respect to t_2 produces two spectra (S_A and S_B) in which the two sets of correlations have the same phase or opposite phase, respectively (center of **Figure 10(c)**). In this simplest case, the Hadamard mask requires taking the sum and difference of the two data sets to produce the two final spectra (right part of **Figure 10(c)**). The advantage of this technique is that all FIDs have information about all signals in the spectrum, producing $n^{1/2}$ improvement in S/N compared to the experiment where n separated selective experiments are performed. Adaptations of this use of Hadamard spectroscopy have been described where the multiplicities of correlations in f_1 have been regenerated from the information in f_2 ; and where narrow spectral windows rather than a single frequency in f_1 have been collected to produce a series of 2D spectra with narrow f_1 windows.

The Fourier transformation is an analytical relationship between the time and frequency domain spectra with specific requirements for calculating the transform between the two domains. By using numerical methods it is possible to produce a simulated spectrum, transform the trial spectrum to produce a calculated time domain signal, compare that signal with the experimental time domain spectrum, and iteratively adjust the trial spectrum so that its time domain signal matches the experimentally collected version of the data. MEM have been used for this purpose. Numerical methods like this remove the restriction imposed by the Fourier transformation technique that sequential data points be sampled. As shown in the left part of **Figure 10(d)**, instead of sampling n separate FIDs with t_1 incremented in steps of $1/\text{sw}_1$ from 0 to $(n-1)/(\text{sw}_1)$, where sw_1 is the spectral width in f_1 , m separate FIDs are collected, where m is much smaller than n . The density of points sampled in t_1

is weighted more heavily in the region closer to $t_1=0$, where the S/N is greater; however, FIDs at longer values of t_1 are also sampled to provide information about the decay of the signal in t_1 . Thus, after MEM calculation to transform $S(t_1, f_2)$ into $S(f_1, f_2)$, better resolution is obtained in the f_1 dimension of the resulting 2D spectrum when compared with the standard Fourier transformation of the spectrum obtained with t_1 incremented from 0 to m/sw_1 .

The above-mentioned methods of 2D NMR treat the t_1 and t_2 dimensions separately, so that if f_1 spectral resolution is desired, the number of points in t_1 must be increased. By removing the condition of treating t_1 and t_2 independently, as required by successive Fourier transformation with respect to t_2 and then t_1 , a condition can be achieved where an increase in the number of points in t_2 can have an impact on resolution in t_1 . This is graphically illustrated in **Figure 10(e)**. In the standard Fourier transformation method of processing 2D, separate traces along t_1 contain information at one specific frequency in f_2 . To increase resolution in f_1 more points are needed along each specific value of f_2 . If the two dimensions are linked in the transform from $S(t_1, t_2)$ to $S(f_1, f_2)$, then sampling additional data points in f_2 can be used to provide more information with regard to the signal behavior in f_1 . On the left side of **Figure 10(e)**, relatively few t_1 increments (m typically 2–8) are sampled. Information along diagonal traces provides information about signals in both the f_1 and f_2 dimensions. Increasing the number of diagonal traces by increasing the number of t_1 , t_2 , or both increments provides additional information about the signal composition in both f_1 and f_2 dimensions. Of course, increasing the number of points in t_2 has far less consequence on the total experiment time than increasing the number of points in t_1 .

The Frydman group has devised a way to rapidly collect complete 2D NMR data sets in which they use PFGs to parse the sample into slices along the direction of the magnetic field (B_0). Each slice is used to produce a signal corresponding to a single t_1 increment. The excitation scheme is organized so that in a single acquisition period a series of echoes is detected during the acquisition time; each echo corresponds to the signal from one of the sample slices, and as a consequence, contributes t_1 increments to the final 2D data set. The resulting echo data is parsed into a 2D matrix and Fourier transformed to produce a 2D spectrum. With this method, a single excitation sequence can be used to produce the entire 2D data set in a matter of seconds. They have named this technique ultrafast 2D NMR.

Recently, commercial dynamic nuclear polarization (DNP) equipment has become available to take advantage of nuclear Overhauser enhancement (NOE) of the signals from less sensitive nuclei such as ^{13}C using the enormous polarization of electrons at low temperature

(1–2 K). Under favorable circumstances the NMR signals are enhanced by a factor of 10 000-fold. The DNP process is inherently slow since the nuclear spins build up polarization at a rate comparable to their T_1 s, which are very long at low temperature. The polarization may take hours to develop for a single acquisition. Although the time-savings are enormous for collection of 1D spectra, the long polarization times and irreproducibility of the process makes DNP incompatible with standard 2D NMR data collection. However, the Frydman group has adapted their ultrafast 2D NMR methods to DNP. Ultrafast 2D techniques are ideally suited to DNP signal enhancement as a single DNP process can be used to produce the entire 2D spectrum.

Reduced dimensionality

Finally, a number of methods have been devised to reduce the dimensionality of n D NMR to $(n - k)$ D NMR. In the simplest form, in a 3D H–X–Y correlation experiment selective pulses (described earlier) can be used to excite individual Y resonances that would normally define a third chemical shift dimension; a series of 2D planes might then be obtained in which the H–X correlations found would identify structures associated with a specific Y nucleus. For a structure with a relatively small number (ρ) of chemically distinct Y nuclei, ρ separate/selective 2D experiments could be performed much more quickly than the corresponding 3D NMR experiment that would sample all of the third dimension space.

In an alternative approach, Szyperski's group adapted the concepts originally associated with accordion NMR experiments, in which two (or more) evolution times are simultaneously incremented to convert the dimensionality of the experiment from n D NMR to $(n - k)$ D NMR. In its simplest form, the two evolution times t_1 and t_2 (containing information about the chemical shifts of A and B nuclei, respectively) in a 3D NMR experiment are simultaneously incremented to produce a 2D NMR spectrum in which the f_1 dimension contains cross peaks at position corresponding to $(\nu_A + \nu_B)$ and $(\nu_A - \nu_B)$. In a 4D experiment, a twofold reduction in dimensionality ($k = 2$) can be realized by simultaneously incrementing the t_1 , t_2 , and t_3 evolution times to produce a $(4 - 2)$ D spectrum in which the peaks would appear at $(\nu_A \pm \nu_B \pm \nu_C)$. The resonances are sorted based on the use of a G-matrix transform (GFT). For samples with relatively few correlations, enormous reductions in dimensionality ($k = 3$ or 4) can be realized without jeopardizing the ability to resolve and identify signals.

UV-visible absorption spectrometers work with light in the wavelength region extending from the far ultraviolet (175 nm) to beyond the red end of visible light (900 nm). Often, the highest specification absorption instruments are able to extend their range into the near-infrared region (NIR).

UV-Visible Absorption Instruments

Typically, in a scanning UV-visible absorption spectrometer, light from a suitable source is transmitted through a monochromator (or filters in a low specification instrument) to yield light of the desired wavelength. This is then passed through the sample and thence to a detector (**Figure 1(a)**). As the monochromator is scanned through its wavelength range, so a spectrum is measured from the detector's response. To improve spectral resolution and accuracy, the highest specification instruments have two or even three monochromators in series.

In contrast, diode array-based instruments, popular as relatively low-cost spectrometers, have a reverse arrangement by having the dispersion of wavelengths postsample by a dispersive optic (e.g., a diffraction grating) that irradiates the diode array detector with the spectrum across its elements. Although commercially available diode array instruments are invariably of lower optical quality than the best scanning instruments, and are limited by their spectral resolution through the number of elements in their array, they do offer the advantage of rapid spectral acquisition, as the complete spectrum across the wavelength range may be acquired almost simultaneously.

A similar 'reverse optics' arrangement, with a post-sample monochromator followed by a detector, has infrequently been incorporated into scanning instruments, albeit rarely on a commercial level (**Figure 1(b)**). Reverse optics instruments, whether diode array or scanning, can be more prone to inducing sample photodecomposition and other photoreactive phenomena, as the full intensity of the light source, unattenuated by a monochromator, is incident on the sample throughout the acquisition.

As the light source and all the optical components of an instrument will have a wavelength dependence, it is necessary to acquire a 'background' spectrum in the absence of a sample with which to correct an acquired sample spectrum. If one wishes to correct simultaneously for the optical properties of a moiety in the sample, such as a solvent in solution studies or the vessel in which it is

Figure 1 Conceptual diagrams of absorption spectrometer configurations: (a) single beam, (b) single-beam reverse optics, and (c) dual beam. contained, then this 'reference' may replace the sample when acquiring the background. Although the background and sample spectra have to be acquired separately (although ideally at proximate times) in a 'single-beam' instrument, many spectrometers have a 'dual-beam' configuration that enables both to be acquired together (Figure 1(c)). In this case, the light is split into two equivalent beams before the sample. One beam passes through the sample, as in the single-beam case, whereas the other passes through the reference. In most current instruments, the two beams are then recombined onto a single optical path to the same detector. The resulting two signals are distinguished by alternately obscuring the beams through the use of 'choppers' (typically a rotating disk with apertures), rotating mirrors (which may be used to generate the two beams alternately), or a combination of the two. Nonetheless, for studies of the highest precision, a sequential background should be acquired to ensure complete correction for the sample optical path, which will inevitably differ slightly from that of the reference path in a dual-beam arrangement.

The use of oscillating signals brings a further benefit in the ability to use AC rather than DC detection circuitry, where phase lock amplification can be used to best advantage, particularly if a dark period during which light is completely obscured from the detector is also introduced to provide a zero-transmission level. This advantage is equally applicable in single-beam configurations and therefore is to be found in virtually all scanning instruments. The drawback of employing oscillating signals is that rapid phenomena, such as in kinetic studies, may be immeasurable on the oscillation time scale. In these cases, a dual-beam configuration with two separate detectors and continual illumination may be more appropriate.

Instruments are generally limited by the maximum absorption (measured in absorption units, AU) they can measure due to stray light (see later) and signal-to-noise concerns. Typical limits are, in practice, up to 1 AU for diode arrays and single monochromators, up to 2.5 AU for routine double monochromators, and up to 4 AU for the highest specification double monochromator instruments. A once popular technique, now reappearing in the latest instrumentation, for aiding the precise absorbance determination of highly absorbing samples is to introduce an attenuator into the reference beam in a double-beam configuration. In so doing, the relative absorbance of the sample to the reference is reduced to around 1 AU, so achieving near optimal conditions regarding signal-to-noise. However, stray light will continue to exert its effects.

As with all instrumentation, proper care and maintenance are essential for correct functioning. Notwithstanding this, UV-visible absorption spectrometers are very reliable if a few precautions are taken with their operation. In particular, instruments should be sited in

vibration-, vapor-, and dust-free environment with low humidity and minimal temperature variation. For use in the UV region, it is necessary to purge the instrument with dry evaporated nitrogen, so as to exclude oxygen, which absorbs below 200 nm and will otherwise generate reactive ozone that damages the optical components. Moreover, the discipline of continuously purging with nitrogen, whatever the wavelength region, protects the optical components from airborne contaminants and prolongs their life.

Light Sources

The key requirements for a light source in UV-visible instruments are an adequate coverage of the spectral range with sufficient intensity together with stability of output. Deuterium arcs and tungsten filament lamps are frequently employed in tandem for the lower (180–350 nm) and higher (330–900 nm) wavelength region, respectively. Alternatives for the higher wavelength region include quartz halogen lamps, which are essentially a tungsten filament in a halogen atmosphere within a quartz envelope. These operate at higher temperatures than traditional tungsten filaments, the halogen prolonging the life of the lamp through reacting with vaporized tungsten to minimize blackening of the envelope.

For the complete wavelength region (175–1000 nm) high-intensity xenon arcs may be employed. The output of such arcs, particularly those above 100 W, are of great value in fluorescence instruments where high intensity is a prerequisite, but are usually considered unnecessarily powerful for absorption spectrometers, particularly given their heat generation. Other alternatives, currently for specialist use, include tuneable lasers (which may obviate the need for monochromators) and pulsed arc lamps (which give a broad band of intense radiation, like steady-state arcs, but with much reduced heat generation).

Monochromators

The simplest of wavelength selectors is a set of optical filters in a movable mount such that an individual filter may be placed into the optical path. However, they are wholly inadequate for spectroscopy, except for the most basic of the instruments. Nonetheless, they may be fruitfully employed to prefilter light before a monochromator to reduce stray light and attenuate the incident radiation of the optical elements.

The simplest of monochromators consist of a rotatable diffraction grating or prism together with a number of mirrors to guide the beam from the entrance to the exit slit/aperture. As the grating or prism is rotated, so the wavelength of light issuing from exit slit varies. The size of the slits through which the light is constrained, coupled with the dispersion of the monochromator's optics, determines the 'spectral bandwidth' (SBW) of the light

produced. Light, nominally of wavelength λ , is better considered as having a distribution of wavelengths, the width of the distribution about λ being given by the SBW. Typically, single monochromators may achieve SBWs of 5–10 nm, whereas for accurate spectroscopy SBWs of the order of 1 nm or less may be appropriate. By coupling monochromators in series, the SBW may be reduced to a more suitable figure and likewise improve stray light performance (see later), albeit with a commensurate loss in light intensity. Alternatively, SBW may be reduced by simply increasing the dimensions of a single monochromator such that the physical linear dispersion becomes larger. However, this can lead to impracticalities and problems with focusing of the beam. Whatever the design, the optimal configuration of components and the use of baffles to deflect and absorb unwanted light are of critical importance.

Diffraction gratings have the advantage of ease of manufacture and relatively constant dispersion with wavelength (i.e., the wavelengths are evenly spread out by the grating). Generally holographic gratings have a higher precision than ruled gratings, although the latter may give greater light throughput away from their central wavelength. With diffraction gratings, the slits may be kept of fixed size to achieve a given SBW independent of the wavelength. In contrast, the dispersion of a prism is highly wavelength dependent, requiring the coupling of the wavelength drive (prism rotation) to the slit mechanisms. However, prisms do have useful transmission and polarization qualities that are of value in other optical instrumentation such as circular dichroism spectrometers.

Sample Compartment

Solution studies are typically carried out using fused quartz rectangular cuvettes (cells) that are, for historical reasons, of 1 cm pathlength. However, many alternative variants are available, including those of cylindrical construction, thermostated flow cells, microcells, and a plethora of specialist types. In particular, pathlengths from 0.001 to 10 cm are readily available from commercial sources, allowing the study of a wide range of sample concentrations and quantities while avoiding problems of excessive or too little absorption. Whatever the cell construction, for reliable results cells must be located in a fixed, reproducible, orientation and position in the sample compartment. Many instrument manufacturers provide a wide range of attachments for controlling the sample, such as thermostated cell holders, stirrers, sippers, and cell auto-changers.

Likewise, there is a vast array of attachments for solid samples, whether for transmission studies or for surface reflectance investigations. In particular, many attachments provide either a method of integrating total reflectance (as in integrating spheres to surround the

sample) or to orientate the surface with respect to the light beam and detector so as to probe specular and diffuse reflectance.

As an alternative, optical fibres allow the study of samples remote from the spectrometer. Essentially a fibre optic redirects the light from the sample compartment to the external sample, with another returning the resultant beam back to the detector. By these means absorption can be monitored by either transmission or reflectance, using remote cells, surface probes, and submersible probes.

Detectors

The detector in a standard UV-visible absorption spectrometer is most frequently a photomultiplier tube (PMT) or a semiconductor-based device such as a silicon diode, the latter being extended to an array in diode array instruments. PMTs have a greater sensitivity and are employed in the most demanding research grade instruments. However, silicon diode devices are considerably smaller, cheaper, and do not require the high voltages necessary with PMTs. Both PMTs and silicon diodes have wavelength dependencies that may also dictate their specific use. More recent detectors include charge-coupled devices (CCD) and photomultiplier arrays, which will no doubt become more commonplace in the future.

Calibration

The two axes of an absorption spectrum, namely, the wavelength (or correspondingly the energy, frequency, or wave number) and the absorption (or transmission or intensity), dictate that these two scales of an instrument be calibrated. The wavelength scale calibration is typically accomplished by the use of either a series of line emissions from discharge lamps, the precise wavelengths of which have been tabulated, or through standard filters with known absorption spectra. For general convenience the filter method is the one of choice. The most common filters used are those of holmium oxide or didymium (a mixture of neodymium and praseodymium) oxide in glass. However, these can be difficult to produce consistently and can show variations of some ± 4 nm in peak positions at the long wavelength end of their useful range (240–685 nm). Therefore, for accurate calibration, it is necessary to use filters provided with a table of determined peak positions from a reputable source such as a national laboratory for standards. As an alternative to glasses, solutions containing lanthanide ions have proved useful, with less variation but a corresponding decrease in convenience.

Historically, potassium dichromate has been the most extensively employed standard for calibrating the absorbance scale. However, in solution numerous species exist in a series of complex equilibria that are sensitive to

pH, concentration, and other environmental factors. Consequently, various organic and inorganic compounds have been investigated as alternatives, although many have other complicating features for calibration to the highest accuracy. Solutions also hold the problems of being a test not just of the instrument, but of the laboratory skills of the scientist preparing them. At present, the most practical method of calibration is through the use of neutral density filters, whose absorbance has been established by a reputable source.

Stray Light

One of the main reasons for an apparent deviation from the Beer–Lambert law for absorption, excluding chemical phenomena specific to a sample, is the effect of stray light. In an ideal spectrometer, only light of the correct wavelength (within the SBW window) that has impinged on the sample would reach the detector and be monitored. Any additional sources of light detected in a real spectrometer may be thought of as ‘stray light.’ Broadly there are five potential sources of stray light:

1. sample fluorescence/phosphorescence/luminescence, etc.;
2. ambient light leakage into the instrument;
3. transmission of light not through or from (in case of reflectance) the sample;
4. imperfections in the monochromator and light source;
5. imperfections in the detector optics.

The first of these, emission by the sample, is invariably weak when it does occur and would only cause problems in the most precise studies or extreme cases. As a molecular phenomenon specific to the sample it is not within the realms of ‘instrumental’ stray light and must be considered on a case-by-case basis.

The second two sources are manifestations of poor instrumental design; instruments should be light tight; and the sample should be sufficiently masked in a blackened compartment to ensure that only light impinging on the sample reaches the detector. This latter condition is sometimes unfortunately overlooked by instrument manufacturers, who may, for example, introduce reflective components in the sample compartment, or cell holders that do not fully mask the cell to within its useable aperture and beyond the dimensions of the light beam.

Finally, the last two sources are, to some degree, unavoidable instrumental stray light. Nonetheless, they can be minimized through careful design and maintenance. Imperfections in the optical surfaces and compromises in the positioning of components in the monochromators, and elsewhere, give rise to unwanted reflections or dispersion. In particular, diffraction gratings are not perfect and furthermore, even in ideal circumstances, they generate repetitions of the wavelength range. Thus the

choice of optimal component configurations, light baffles, and component quality is crucial to the stray light performance.

Reverse optics instruments may similarly exhibit stray light introduced at the detector, post-sample. In particular, diode array instruments may suffer through internal reflections in the optical surface covering the array, leading to apparent illumination of the incorrect array elements.

Polarization

All the optical components, particularly the diffraction grating or prism and the light source, cause the light beam to be polarized. For the study of isotropic samples, with no preferred orientation, via transmission methods this is of little consequence. This is not the case for nonisotropic materials, such as crystals and ordered solids, or reflection measurements where one encounters linear dichroic effects. To avoid polarization artefacts it is necessary to insert depolarizing optics at the appropriate positions in the optical path. However, care must be taken to choose a depolarizer that truly depolarizes at each wavelength, rather than one that simply gives a different, but specific, polarization at each individual wavelength (these are intended for use with white light applications). Suitable depolarizers are often based on multiple scattering (i.e. frosted) glass that, in turn, may give additional stray light concerns.

PMT	photomultiplier tube
UV	ultraviolet

Fluorescence (and phosphorescence) spectrometers essentially illuminate a sample with light (the ‘excitation’) of a chosen wavelength and detect the resultant ‘emission’ of light deriving from fluorescence, luminescence, or phosphorescence phenomena induced in the sample. The excitation would typically be of light within the wavelength region extending from the far-ultraviolet (UV) (175 nm) to the red end of visible ($\approx$ 600 nm), with the corresponding emission being detected in the UV-visible or near-infrared wavelengths ($\approx$ 200–900 nm) as appropriate.

Fluorescence Spectrometers

Fluorescence spectrometers can be divided into either lifetime or steady-state instruments, depending on whether they resolve the temporal behavior of the emission (or more correctly the excited state) or not, respectively.

Figure 1 Conceptual diagram of a fluorescence spectrometer. L = light source, Ex. M = excitation monochromator(s), Ex. P = excitation polarizer, S = sample, Em. P = emission polarizer, Em. M = emission monochromator(s), and D = detector. Copyright of Chiralabs Ltd (2009) with permission.

In both cases, there are strong similarities with single-beam (ultraviolet) UV-visible absorption instruments and the reader is referred to the UV-visible absorption spectrometers section of the encyclopedia for further relevant details, especially regarding stray light.

However, crucially, the levels of photons detected in fluorescence (or equally phosphorescence) are typically much lower than those in absorbance: in the former one is detecting the few photons that are emitted by the sample, in the latter one is detecting those of the light source attenuated by the number absorbed by the sample. As a consequence, certain features are optimized differently for fluorescence. In addition, due to the low levels of photons to be detected, it is extremely important to exclude all sources of ambient light from the instrument.

Fluorescence is typically detected orthogonal to the direction of the excitation beam incident on the sample (Figure 1), so as to spatially delineate the emission photons from those of the excitation beam and minimize those from Rayleigh and Raman scattering, although these always provide a residual level. However, this is not an absolute requirement and instruments to measure the fluorescence in, for example, a well-plate format have nonorthogonal geometries dictated by the location of the sample and the nature of the vessel containing it.

Light Sources

As the fluorescence is directly proportional to the number of photons absorbed by the sample (in the absence of inner-filter/self-shadowing effects of excessive absorption), it is advantageous to employ very high-intensity light sources; xenon arcs are highly suitable. With the higher levels of light impinging on a sample, unwanted photoreactions can be a problem, as can heat generation in the sample, which accelerates all reactions. Alternatives are pulsed sources, which provide broadband radiation over short periods of time and thus may minimize some of the problems of steady-state arcs. Furthermore, in lifetime instruments they provide a means of determining the time lag between absorption and subsequent emission of the photons by the sample – the emission lifetime. In this respect pulsed lasers and flash lamps such as hydrogen arcs are popular. For very portable, low-powered, or small devices, high-intensity, light-emitting diodes have been employed successfully as light sources.

Monochromators

To distinguish the wavelength dependencies of a sample's excitation and emission spectra, monochromators are placed in both the excitation and emission optical paths. In very basic instruments, filters may be substituted for monochromators. Similarly, for instruments operating at a single excitation wavelength, laser sources can be used to good effect and negate the need for an excitation monochromator. The emission-side monochromator and detector may also be replaced with a fixed dispersive element (e.g., a diffraction grating) and a solid-state array detector.

The selection of excitation wavelength and detected emission wavelength may be independently controlled. Thus, the excitation wavelength may be fixed and the emission wavelength scanned to give the emission spectrum, or vice versa to give the excitation spectrum. On many of the higher specification instruments, it is possible to automatically scan both the emission and excitation wavelengths to give an excitation–emission 2-D maps or fixed offset maps.

Additional excitation intensity may be achieved by greater spectral bandwidths employed on the excitation side, although this may compromise the spectral resolution of the results. Similarly, the number of photons detected can be increased by modestly increasing the spectral bandwidth on the emission side. However, again this will have a corresponding effect on spectral resolution.

Sample Compartment

Solution studies are typically carried out using fused quartz rectangular cuvettes (cells) that have orthogonal faces optically transparent and flat; for historical reasons, these are typically of 1 cm pathlength. However, many alternative variants are available, including thermostated flow cells, micro cells, and a plethora of specialist types. Whatever the cell construction, for reliable results cells must be located in a fixed, reproducible orientation and position in the sample compartment. Many instrument manufacturers provide a wide range of attachments for controlling the sample, such as thermostated cell holders, stirrers, sippers, and cell autochangers.

Likewise, there are numerous attachments for solid samples. As an alternative, optical fibres allow the study of samples remote from the spectrometer. Essentially, a fibre optic redirects the light from the sample compartment to the external sample, with another returning the resultant beam back to the detector. By these means, fluorescence can be monitored using remote cells, surface and submersible probes. Adaptations to fluorescence spectrometers such that they can measure fluorescence

from samples in a well-plate format, or vials and tubes are also available.

Detectors

The detector in a standard fluorescence spectrometer is most frequently a photomultiplier tube (PMT) or a solid-state semiconductor-based device; PMTs generally have a greater sensitivity and are employed in many of the most demanding research-grade instruments. More recent detectors include charge-coupled devices (CCD) and photomultiplier arrays, which will no doubt become more commonplace in the future. In the most sensitive of instruments, the detector is cooled to reduce noise and thus improve the signal-to-noise levels.

Calibration

The two axes of a fluorescence spectrum, namely, the wavelength (or correspondingly the energy, frequency, or wave number) and the fluorescence intensity (or photon counts), dictate that these two scales of an instrument ideally be calibrated.

The wavelength scale calibration, that is, the adjustment of the monochromators to ensure the correct wavelength, can be accomplished by the use of either a series of line emissions from discharge lamps, the precise wavelengths of which have been tabulated, or through standard filters with known absorption spectra. For general convenience, the filter method is the one of choice. The most common filters used are those of holmium oxide or didymium (a mixture of neodymium and praseodymium) oxide in glass. However, these can be difficult to produce consistently and can show variations of some ± 4 nm in peak positions at the long wavelength end of their useful range (240–685 nm). Therefore, for accurate calibration, it is necessary to use filters provided with a table of determined peak positions from a reputable source such as a national laboratory for standards. As an alternative to glasses, solutions containing lanthanide ions have proved useful, with less variation but a corresponding decrease in convenience. As a further check, the spectral characteristics of many common fluorophores are known and can be employed as secondary calibrants of wavelength.

In contrast, many fluorescence studies are carried out without recourse to calibration of the fluorescence intensity or the correction for instrumental response variations with wavelength, or even with time. For some investigations this is adequate, but the reasons for not calibrating stem primarily from its difficulty rather than its irrelevance; for absolute measurements, intensity calibration is essential.

To correct excitation spectra, it is necessary to determine the wavelength dependence of the light intensity of the excitation side of the instrument, with the emission side fixed. A common method is to employ a 'quantum counter'; essentially a compound whose absorption spectrum (at an appropriate concentration) is such that more than 99% of all the exciting photons are absorbed over a sufficiently wide wavelength range and whose emission spectrum and quantum yield are independent of the excitation wavelength over this range. The most frequently used quantum counter is rhodamine B in glycerol or ethylene glycol (at 3–8 g l⁻¹). This solution exhibits constant (to within 2%) fluorescence efficiency at 610–620 nm when excited in the range 350–600 nm, and only $\pm 5\%$ variation for excitation between 250 and 350 nm. Measurement of the apparent excitation spectrum of such a sample, monitored at an emission wavelength between 610 and 620 nm, allows direct determination of the wavelength dependence of the excitation side of the instrument.

The effectiveness of this method has led to instruments in which a quantum counter is incorporated into the design by diverting a portion of the excitation light to a separate quantum counter and detector. Although such a system importantly allows for correction of any temporal variations while measurement on samples is ongoing, it does introduce a difference in the optical path from that of the true excitation beam, with a potential inaccuracy.

Determination of the wavelength dependence of the emission side of an instrument is more problematical. Ideally, light from a 'standard lamp,' that is, one whose calibrated spectral distribution is known, is directly introduced into the emission optical path from the sample compartment. Measurement of the apparent 'emission' spectrum and comparison with the known true distribution of the lamp give the wavelength characteristics of the emission side.

One practical variation of this method is to employ the light from the excitation side of the instrument, for which the wavelength characteristics have already been determined via, say a quantum counter. To direct this light into the emission optical path, it is necessary to place a reference scatterer into the sample compartment. Such scatterers must have no appreciable wavelength dependence over the wavelength range of interest (mirrors, while achieving the redirection, have wavelength dependencies that make them poor choices). Common choices are flat cakes of magnesium oxide (MgO) or barium sulfate with potassium sulfate binder (BaSO₄ in K₂SO₄), which can be mounted in the sample position at an angle of 45° to both the excitation and emission optical paths. When using such devices, it is important to take care that the light intensity reaching the detector is not excessive, as this would lead to saturation, inaccurate

measurement, and possible damage to the detector; the use of narrow spectral bandwidths or attenuators may be required in these circumstances.

As an alternative to standard lamps and their derivatives, there are numerous compounds whose absolute fluorescence spectra have been documented and may be employed to deduce the emission wavelength characteristics of the instrument. Nonetheless, the calibration of the excitation arm is still an essential procedure before the emission arm can be likewise calibrated.

Stray Light and the Inner Filter Effect

One of the main reasons for an apparent deviation from a linear response of a sample with concentration is the effect of stray light. In an ideal spectrometer, only light of the correct wavelength (within the spectral bandwidth window) would illuminate the sample and thence only fluorescence of the correct wavelength would reach the detector and be monitored. Any additional sources of light in a real spectrometer may be thought of as 'stray light.' Broadly there are six potential sources of stray light in a fluorescence instrument:

1. scattering from the sample;
2. fluorescence/scattering of the cell, etc.;
3. ambient light leakage into the instrument;
4. scattering/transmission/reflection of light by routes other than via the sample;
5. imperfections in the monochromators and light source optics;
6. imperfections in the detector optics.

The first of these, scattering by the sample, can be a serious issue when working with emission wavelengths close to the excitation wavelength. As a phenomenon specific to the sample, it is not within the realms of 'instrumental' stray light and must be considered on a case-by-case basis. However, it also provides a mechanism for additional 'second-order' anomalous signals, which may appear at distant wavelengths, due to the characteristics of diffraction-grating monochromators (see below), the scattered light masquerading as fluorescence.

The sources (2), (3), and (4) are manifestations of poor instrumental design; instruments should be light-tight and the sample should be sufficiently masked in a blackened compartment to ensure that only light impinging on the sample reaches the detector. This latter condition is sometimes unfortunately overlooked by instrument manufacturers, who may, for example, introduce reflective components in the sample compartment, or cell holders that do not fully mask the cell to within its useable aperture and beyond the dimensions of the light beam.

Finally, the last two sources are, to some degree, unavoidable instrumental stray light. Nonetheless, they can be minimized through careful design and maintenance. Imperfections in the optical surfaces and compromises in the positioning of components in the monochromators, and elsewhere, give rise to unwanted reflections or dispersion. Thus, the choice of optimal component configurations, light baffles, and component quality is crucial to the stray light performance. Diode array instruments may suffer through internal reflections in the optical surface covering the array, leading to apparent illumination of the incorrect array elements.

In particular, diffraction gratings are not perfect and furthermore, even in ideal circumstances, they generate repetitions of the wavelength range – the ‘higher-order’ diffractions alongside the first-order (principal) diffraction, albeit of typically weaker intensity. The most important of these, the second-order diffraction, will give light of a wavelength half that of the first-order diffraction but along essentially the same trajectory. Thus, the second order transmission of the emission monochromator of the principal excitation wavelength, if scattered by particles in a sample, can masquerade as fluorescence at twice the wavelength of the principal excitation wavelength. Consequently, care must be taken in interpreting fluorescence signals observed at multiples of the excitation wavelength. As a corollary, this anomaly can be used to advantage in allowing the monitoring of scattering alongside fluorescence without excessive photon counts for some samples.

Excessive absorption by the sample can also provide a means for both stray light to have an exaggerated effect and for the appearance of anomalous fluorescence intensities. For example, if the absorption of a sample in a fluorescence cell is *c.* 1 AU (along the direction of excitation), then the intensity of the excitation light at the center of the cell will be only *c.* 32% of that at the front face (intensity is logarithmically related to absorption). Clearly, if the fluorescence is measured from this central portion it will be of much lower intensity than that at the front face, potentially giving the impression that the fluorescence is quenched or diminished. This ‘inner-filter’ effect can be easily avoided by ensuring that concentration of the sample, together with the dimensions and geometry of the cell, is such that the absorption at the excitation wavelength is kept below 0.1 AU.

Fluorescence Anisotropy and Polarization

As in absorption spectroscopy, instrumental polarization effects can yield unwanted artifacts and therefore it is appropriate to introduce depolarizers into the optical path before and after the sample if the aim is to monitor the true unpolarized fluorescence spectrum.

Unfortunately, this will reduce the light levels commensurately and is therefore frequently not pursued. Other methods, involving the use of polarizers set at ‘magic angles’ to minimize some unwanted polarization effects, have been devised but are even less frequently employed.

However, deliberate polarization can be used to great advantage in probing the environment and motion of fluorescent molecules and groups in larger macromolecules. In this case, rotatable plane polarizers are inserted in the optical path just before and after the sample; spectra are acquired in the four possible combinations of the polarizers, each in the horizontal or vertical orientation relative to the ‘horizontal’ plane defined by the excitation and emission optical paths. By comparison of the four spectra, the mobility of the fluorescent group during the lifetime of the excited state can be deduced.

Fluorescence Lifetime Instruments

Lifetime instruments share most of the optical arrangement of steady-state instruments. Indeed, there are commercial instruments that combine both into one versatile spectrometer. The essential optical difference is in the use of intense pulsed light sources, with an emission pulse width typically of the order of 1 ns or less. By coupling the detector and light source trigger with sophisticated electronics and postacquisition processing, it is possible to correlate the time between the absorption and subsequent emission of photons by the sample. Essentially, the excitation pulse corresponds to the absorption profile in time. In *time-correlated single photon counting methods*, the delay for the first photon to be subsequently detected is then recorded. This is repeated many thousands of times to give a statistical distribution from which the emission time profile can be deconvoluted.

Alternatively, if the lifetime is sufficiently long, as in phosphorescence, then the complete decay curve of emitted photons from a single excitation pulse can be directly monitored – the *pulse excitation method*. Finally, rather than employing a flash lamp to provide a pulse of excitation, the intensity of continuous excitation can be modulated and the phase lag of resulting oscillations on emission intensity observed – the *phase-resolved method*. Whichever method is adopted, in turn the data can be analyzed in terms of the fluorescence or phosphorescence lifetimes of the molecular species involved.

Imaging Instruments

The advent of imaging detectors, such as CCD cameras and more recently photomultiplier arrays, has prompted

the development of monochromators that are able to spectrally disperse the individual pixels of an image, while preserving the spatial integrity of the image. Consequently, absorption and fluorescence instruments have been developed that are able to produce a spectroscopic image of a sample, each pixel of the image being a complete spectrum. Such instruments have great utility in the investigation of inhomogeneous material for which traditional methods are only able to give spatially averaged results, especially if the imaging system is a microscope.

Introduction

Only a few methods are available for the determination of the absolute configuration of chiral molecules. The most common are synthesis by chemical degradation from a molecule with reliably known stereochemistry, the X-ray method of Bijvoet, or the measurement of electronic circular dichroism (ECD). The chemical method has often been used in the history of chemistry when no other methods were available, but it is too time-consuming to be generally applicable. The X-ray method is surely the most important, as it gives starting points for all other methods, but it cannot be applied to molecules that are not crystallizable and it is often too time-consuming and comparatively demanding. The measurement of ECD requires a suitable chromophore. If none of these methods is practicable, the measurement of vibrational circular dichroism is a good choice. Since vibrational circular dichroism (VCD) and Raman optical activity (ROA) are complementary techniques (a stereochemical problem that cannot be solved by one technique can most probably be solved by the other), the interested reader should also consult appropriate articles on ROA.

The history of VCD is marked by instrumental advances: the early instruments were useful only in the near-IR, first for measuring O–H and N–H stretching vibrations and their overtones, advancing to the C–H stretching region, later covering the C=O stretching vibration, and finally intruding into the fingerprint region. Advances in theory are also clearly discernible: first, simple coupled oscillator models were compared to the experimental spectra, then semiempirical calculations, were made, later Hartree–Fock (HF) *ab initio* calculations, and now mainly density functional theory (DFT) calculations.

Stereochemistry of Small Chiral Molecules

In principle, the stereochemistry of a molecule can be determined by comparing the sign of a single band of one

enantiomer with the calculated sign of that band. Unfortunately, the calculations are still not accurate enough for this method. One has to compare the enantiomer's spectrum in a larger spectral region with the calculated spectra of both configurations and then look for the best fit. In the early days of VCD spectroscopy, when the theory of VCD was not well developed, it was possible to derive 'chirality rules' for some classes of compounds.

The first publication of a single-molecule VCD effect appeared in 1974. (*S*)-(+) and (–)-(–)-2,2,2-trifluoromethylphenylethanol [1] and (*R*)-(–)-neopentyl-1-*d*-chloride were examined using the C–H stretching vibration and its respective C–D analogue. As the signal-to-noise ratio of these first spectra was very low, the former compound was re-examined the following year by another group.

[1]

NMR data together with VCD data (O–H and C=O regions) were used to access the conformation of dimethyl tartrate and (2*S*)-(–)-malic acid dimethyl ester. A later investigation on the conformations of tartaric acid and its esters used *ab initio* calculations to find that the *trans*-COOH conformation with hydrogen bonding was the most stable. These results fit well with the VCD intensities in the C*–O stretching region of the examined compounds if charge flow along the C*–C* bond is assumed.

Using an empirical force field of the Urey–Bradley type, the infrared Raman, VCD and ROA spectra of chlorofluoroacetic acid and its anion were readily interpreted.

In an investigation of the O–H stretching vibration of the (*R*) enantiomer of 2,2-dimethyl-1,3-dioxolane-4-methanol [2], the conformer containing an intramolecular hydrogen bridge showed a positive VCD effect

at 3600 cm^{-1} . The free form of the alcohol showed no measurable VCD band.

Spectra of substituted allenes showed a correlation of the sign of the VCD for the asymmetrical stretching vibration of the $\text{C}=\text{C}=\text{C}$ moiety ($\approx 1950\text{ cm}^{-1}$) with the absolute configuration. Thus for an (*S*) configuration, the VCD was positive. Judging from two 1-halo-3-*t*-butyl allenes, such a correlation also seems to exist in the $\text{C}(\text{X})\text{--H}$ stretching mode ($\approx 3050\text{ cm}^{-1}$).

Anisotropies from $+1.5 \times 10^{-4}$ to $+4.5 \times 10^{-4}$ were found for the VCD in the methine stretching mode of hydroxyacid methyl esters, whereas dimethyl-*d*₆-2,3-*O*-benzylidene-*C*-*d*₁-*L*-tartrate and (*S*)-methyl-2-chloropropionate showed only small VCD signals.

(*R*)-2,2'-Dihydroxy-1,1'-binaphthyl [3] was examined in the O--H stretching region and from 950 to 1700 cm^{-1} . For (1*R*, 5*R*, 6*R*)-(–)-spiro[4.4]nonane-1,6-diol [4], the theoretical VCD spectra were produced using vibronic coupling theory at the 6-31G level. A comparison of the crystal structure of the ketal of the compound with optically pure (+)-5 α -cholestan-3-one confirmed the results of the VCD determination.

Isoflurane [5] and desflurane [6] are relatively new fluorine-containing anaesthetics. Unlike older anaesthetics such as diethyl ether or chloroform, they are

Figure 1 VCD of desflurane. The experimental spectrum shows the (–)-enantiomer (corrected, as the original label incorrectly read (+) due to a confusion); 0.2M solution in CCl_3 . The theoretical calculations were done on the (*R*) configuration. Reprinted with permission from Polavarapu PL, Cholli AL, and Vernice G (1992) Determination of absolute configurations and predominant conformations of general inhalation anesthetics: Desflurane. *Journal of Pharmaceutical Sciences* 82: 791–793. © 1992 American Chemical Society.

chiral molecules; VCD spectra can be taken and, by comparison with theoretical spectra, their absolute configuration can be determined. This is especially valuable as the enantiomers have different biological activities; for example, the (+)-isomer of isoflurane is nearly twice as effective in activating the potassium current as the (–)-isomer. Experimental and theoretical spectra are shown for desflurane in **Figure 1**. The same assignment has been made for both compounds: the (*R*) configuration for the (–)-isomer and accordingly the (*S*) configuration for the (+)-isomer. For each isomer of desflurane, two dominant conformations were found. In a reinvestigation of the compound using DFT methods (see **Table 1**) and large basis sets, the configurational assignment was confirmed, but three different conformers contributing to the experimental spectrum have been proposed. A study on a third volatile anaesthetic used the same high level of theory: for (–)-1,2,2,2-tetrafluoroethyl methyl ether the

Table 1 Models/methods cited

LMO	Localized molecular orbital
MFP	Magnetic field perturbation
APT	Atomic polar tensor
VCT	Vibronic coupling theory
EXC	Excitation scheme
HF	Hartree-Fock
DFT	Density functional theory

(*R*) configuration was derived from the VCD spectrum and the *trans*-conformer was found to be dominant in CCl₄ solution.

The enzymatic synthesis of (*2R*)-(+)-(²H) cyclohexanone and *trans*-(2,6-²H₂)cyclohexanone has been reported together with the CD spectrum and the VCD spectrum in the C–H and C–D region.

For (*3R*)-(+)-methylcyclohexanone [7] in the C–H stretching and deformation region, no temperature dependence of the VCD was found. This leads to the conclusion that only one conformation is present in solution. Four of its chiral deuterated isotopomers were also examined in the C–H and the C–D regions. In the first report of VCD in the CH₂ bending region, 3-methylcyclohexanone and (+)-*trans*-1,2-cyclopropane dicarboxylic acid dichloride were investigated. The spectra of (*R*)-(+)-3-methylcyclohexanone and (*R*)-(+)-3-methylcyclopentanone showed negative bands in the region of the overtones ($\nu = 4$) of the C–H stretch, which had a distinctly larger rotatory strength in the case of the cyclopentanone derivative. The very first investigation in the poorly accessible 370–620 cm^{−1} region was performed on (*R*)-3-methylcyclohexanone. The result was compared successfully with *ab initio* calculations.

Small rings (three- and four-membered) have been of great interest among VCD spectroscopists. The rings

have a rigid structure and the compounds are small enough to allow the theoretical spectra to be calculated in reasonable time. Optically active cyclopropanes were studied in the C–H stretch and CH₂ bending regions, and deuterated compounds in the respective regions. Spectra could readily be interpreted using the FPC model. The C=O region of a dimethyl ester and the C≡N stretching region of a dinitrile were also investigated. Here the coupled oscillator model could be used with advantage. The model failed for deformational modes.

In the VCD spectra of *trans*-2-phenylcyclopropane carboxylic acid and similar compounds, the symmetrical stretching vibration of the methylene group of the cyclopropane ring always showed a negative sign for the (*1R*, *2R*) configuration.

With (*S*)-(+)-(^{1,2-²H₂})cyclopropane in the gaseous phase, the region above 2000 cm^{−1} could only be resolved to 7.2 cm^{−1}, but from 900 to 1500 cm^{−1} a resolution of 1 cm^{−1} was reached for the first time, allowing the observation of P, Q, and R branches in the VCD spectrum.

The crystal structure of the triply bridged diborate ester tris(*trans*-1,2-cyclopropanediyl)dimethylene diborate [8] has been determined, and its VCD spectrum has been measured from 3150 to 2750 cm^{−1} and from 1500 to 950 cm^{−1}.

The symmetry of oxirane is lowered from *C*_{2v} to *C*₂ by partial deuteration. The resulting (*S,S*)-(2,3-²H₂) oxirane [9] exhibits two modes in the C–H as well as in the C–D stretching region of the infrared spectrum, corresponding to two couplets in the VCD spectrum. Their intensities are affected by a ring current mechanism (C–H) and a Fermi resonance (C–D). The molecule has also been investigated in the gaseous phase.

The VCD spectrum of (*S*)-(-)-epoxypropane [10] in the liquid and in the gaseous phase shows the splitting of

the degenerate vibrational modes of the methyl group. Its analysis verified the VCD theory of the perturbed vibrational degenerate modes. Using a resolution of 1 cm^{-1} , the CD in the rotational-vibrational spectrum of (*R*)-(+)-methyloxirane has been measured with the result that the Q branch in some bands has the opposite sign to the R and P branches. This can be explained if methyloxirane (in spite of its chirality) is an approximate symmetrical top.

[10]

The absolute configuration of *trans*-2,3-dimethyloxirane [11] (*2R,3R* for the (+)-enantiomer) has been derived from the VCD spectra and *ab initio* calculations and is consistent with that determined by complexation chromatography.

[11]

The vibrational circular dichroism of both enantiomers of methyl thiirane [12] has been measured in CCl_4 , in CS_2 , and in the gaseous phase. The experimental spectra have been compared with a wide variety of theoretical calculations.

[12]

An extensive analysis of the experimental VCD of *trans*-2,3-dimethyl thiirane [13] and its 2,3- d_2 -isotopomer was published for $850\text{--}1650\text{ cm}^{-1}$. Comparing the experimental spectra with various calculations, the best results were obtained using the VCT model and the basis set $6\text{--}31\text{G}^{*(0,3)}$.

[13]

(*2R*)-2-Methylaziridine exists in solution as a mixture of the invertomers. According to *ab initio* calculations, the ratio of (*1R,2R*)-2-methylaziridine (*trans*) [14] to (*1S,2R*)-

2-methylaziridine (*cis*) should be 70 to 30. The experimental VCD spectrum is dominated by the effects of the *trans* isomer, as this not only is in excess but also shows greater rotatory strengths.

[14]

The heterocycles 1,2- and 2,3-dimethylaziridine were measured from $1500\text{ to }1800\text{ cm}^{-1}$, and the experimental VCD spectra were compared with theoretical calculations using the VCT model.

Comparison of the experimental spectra of *trans*-1,2-dideuteriocyclobutane [15] with the FPC, as well as with the LMO model shows the former to be considerably more reliable.

[15]

The synthesis, normal coordinate analysis, and VCD spectrum have been reported for (*2S,3S*)-dideuteriobutyrolactone [16]. Comparison of the latter with *ab initio* calculations using the MFP method and basis set $6\text{--}31\text{G}^{**}$ yielded good qualitative agreement.

[16]

In a study on the VCD of (*3R,4R*)-dideuterio-cyclobutane-1,2-dione [17], the experimental spectra were compared with the calculated rotatory strengths using the MFP model, with good agreement.

[17]

In the region of methyl deformational modes and in the C-H stretching region, the VCD of α -phenylethylamine, α -phenylethanol, α -phenylethylisocyanate,

p-bromophenylethylamine, and (*S*)-methyl mandelate [18] was examined. The bands near 1450 cm^{-1} were explained by interaction of the CH_3 deformational mode with an energetically neighboring phenyl vibration.

With 1-phenylethanol, 1-phenylethanethiol, 1-chloro-1-phenylethane, D- α -phenylglycine-*N*- d_3 , and (*S*)-methyl mandelate, the VCD of the methine stretching vibration is enhanced by ring currents. For methyl mandelate, a very large value of $\Delta\epsilon = 5 \times 10^{-3}$ is found for the O–H stretching vibration.

α -Phenylethylamine, α -phenylethyl alcohol, α -phenylethyl isocyanate, and methyl mandelate were measured in the $1625\text{--}860\text{ cm}^{-1}$ region. The VCD effects, which occur at 1368 and 1182 cm^{-1} with phenylethylamine, were correlated with the stereochemistry of the molecules.

A simple chirality rule was derived for six phenylcarbinols: orienting the fourth substituent to the back and arranging the remaining three substituents in the order OH–Ph–H clockwise, one finds a negative VCD band at 1200 cm^{-1} ; orienting them counterclockwise results in a positive effect.

Deuterated phenylethanes were observed in the region from 3100 to 2000 cm^{-1} . All aliphatic C–H and C–D stretching vibrations could be assigned.

The measurement and the theoretical calculation of the VCD spectrum of 6,8-dioxabicyclo[3.2.1]octane [19] was presented together with a detailed *ab initio* normal coordinate analysis using the APT and the FPC models. In another study, mono- and dimethyl derivatives of 6,8-dioxabicyclo[3.2.1]octane were treated the same way, but compared with calculations of higher accuracy (see also the pheromone [34]). The determination of absolute configuration by VCD has been made for some *exo*-7-derivatives of 5-methyl-6,8-dioxabicyclo[3.2.1]octane ($\text{R} = \text{H}, \text{OH}, \text{Br}, \text{or } \text{CH}_3$). Using recurring patterns in the $1100\text{--}1400\text{ cm}^{-1}$ region, the chiral unit – $\text{C}^*(\text{CH}_2\text{R})\text{X}-$, with $\text{X} = \text{O}$ or S was detected in rings of different size. The signs of these patterns correspond to the absolute configuration.

The growing use of VCD spectroscopy, with comparisons against *ab initio* computed spectra, has established the technique as a powerful tool for a priori stereochemical assignment, especially where there is a paucity of experimental reference data. With the expanding number of examples published, it has become clear that the conformational dynamics and populations of conformers adopted by flexible molecules must be incorporated into the analysis to fully represent the species and provide a faithful representation of the spectra computationally. Consequently, a comprehensive conformational analysis to provide Boltzmann population statistics is often a prerequisite to the computation of VCD spectra.

Crystals

The first sample in which VCD was detected unambiguously was a thin slice of a crystal of α -nickel sulfate hexahydrate. The compound crystallizes as tetragonal bipyramids in the narrow temperature range $31.5\text{--}53.3^\circ\text{C}$. The same paper, which was published in 1973, also reported the VCD of $\alpha\text{-ZnSeO}_4 \cdot 6\text{H}_2\text{O}$. As nickel sulfate is an achiral molecule, the VCD bands can be ascribed to vibrations of the chiral array of water molecules. Five main bands were found: at 2300 cm^{-1} ($\nu_2 + \text{librations}$), at 4000 cm^{-1} (ν_3 or $\nu_2 + \text{librations}$), at 4200 cm^{-1} , at 4350 cm^{-1} , and the first part of a strong negative band at 5100 cm^{-1} ($\nu_2 + \nu_3$), which was expected to be symmetrical. α -Nickel sulfate has been re-investigated by the author's group and the latter band showed a sawtooth shape with the steeper descent on the side of shorter wavelength (**Figure 2**). We also found a new band at 2070 cm^{-1} , which, owing to lower resolution, had formerly only been detected in the absorption spectrum and had been attributed to the first overtone of the ν_3 vibration of the SO_4^{2-} ion (species F_2 at 1104 cm^{-1}).

Liquid Crystals

Studies of the optical activity of liquid crystalline solutions in the infrared region were published one year before the publication of single-molecule VCD effects. Using a solution of 2 mol% *d*-carvone in a liquid-crystalline eutectic of the isomeric *N*-oxides of *p*-methoxy-*p'*-*n*-butylazobenzols, huge effects were observed from the liquid crystal forced into a helical arrangement (cholesteric state) by the chiral solute. The liquid crystal acts as a molecular amplifier and reliably allows the determination of absolute configuration, using only tiny amounts of substance. Later the same year, the VCD of a solution of 2% (–)-menthol in *N*-(*p*-methoxybenzylidene)butylaniline was published. Again the effects were extraordinarily large.

Figure 2 VCD (upper) and absorbance (lower) spectra of a thin crystal slice of α -nickel sulfate hexahydrate ($d = 63 \mu\text{m}$, cleaved parallel (001) as shown in inset). No spectrum could be taken of bands with absorbance >2 .

Infrared circular dichroism can also be measured using an ATR arrangement consisting of a wire polarizer followed by a KRS5 half-cylinder as ATR element. The spectrum of a 1% solution of cholesteryl chloride in the liquid crystal ZLI-887 was recorded from 4000 to 400 cm^{-1} and compared favorably with a VCD spectrum recorded by the common-beam technique.

Organometallic Compounds

Relatively few papers have been published on the VCD of organometallic complexes. This may be because the common organic ligands are achiral and chirality has to be sought in the arrangement of the ligands around the central atom. The very first spectra of organometallic compounds were of electron transitions of Pr^{3+} -tartrate complexes down to 2000 cm^{-1} . The next published spectra of real vibrational transitions featured the C-H region only. These studies were on tris(3-trifluoromethylhydroxymethylene-*d*-camphorato) complexes of europium and praseodymium. Studies on complexes with amino acids, ethylenediamine, and acetylacetate followed.

The two diastereomeric complexes Δ - and Λ -bis(acetylacetonato)(L-alaninato)cobalt(III) give rise to VCD

spectra that can be explained using the degenerate coupled oscillator model (antisymmetric C=O stretching at 1522 cm^{-1}) and the ring current mechanism (N-H stretching). The appearance of the latter is illustrated by the fact that while they give nearly equal absorption spectra, the VCD of the Δ -isomer is nearly ten times larger than that of the Λ -isomer.

The spectral data (C–H stretching) of five copper complexes of amino acids and (Δ) α' -tris(L-alaninato)cobalt(III) have been obtained. As for the parent amino acids at pH values favoring hydrogen bonds, one detects an enhancement of the methine band by ring current effects. This is even larger as a result of the better closure of the ring by the transition metal ion.

Complexes of trivalent cobalt and chromium with ethylenediamine have also been examined by VCD. Again substantial enhancements of the VCD effects by ring currents are found for the N-H and C-H stretching vibrations.

The peptide *cyclo*-(Pro-Gly)-₃ forms complexes with different alkali and alkaline earth metals that show spectra with sensitivity to the conformation of the peptide; the arrangement of the carbonyl groups is especially of interest. The solvent plays the most important role

in the development of conformation. The size of the ion-binding cavity formed by the carbonyl groups and the size and charge of the cation are only of secondary importance.

In studies of the interaction of two deoxyribo-oligonucleotides with divalent manganese ions, the resulting changes in the VCD spectra of $d(GC)_{20} \cdot d(GC)_{20}$ and $d(ATGCATGCAT) \cdot d(ATGCATGCAT)$ were interpreted in terms of structural changes.

Biochemical Applications

Terpenes

The first VCD investigation on camphor [20] observed the C–H stretching in the principal region as well as in the first overtone and combination regions; the first overtone of the C=O stretching was also measured. Later reports showed VCD also in the mid-IR and presented calculational results.

Inherently dissymmetric chromophores, meaning groups that do not gain their chirality only from the influence of their neighborhood, have always been of interest to investigators studying optical activity, including VCD spectroscopists. The sequence of signs could be correctly predicted for 15 different molecules (including cyclohexanones, menthone [21], pinenes, pulegone, and other natural products) featuring the $CH_2-C_2H-C^*H$ moiety.

Using an FT-VCD spectrometer, the spectra of (+)-3-methylcyclohexanone, (+)-carvone [22], and (–)- α -pinene [23] were observed in the mid-IR region; a higher signal-to-noise ratio and twice as great anisotropy were obtained than with dispersive instruments. Matrix-isolated molecules feature even larger anisotropies. Accessing the band at approximately 2920 cm^{-1} , one finds values of

5.4×10^{-4} for (–)- α -pinene and -6.5×10^{-4} for (–)- β -pinene, which really are record values (excepting the huge value of 0.02 for methaemoglobin azide).

For the six monoterpenes (*S*)-(–)-limonene, (*R*)-(+)-limonene, (*S*)-(–)-perillyl alcohol, (*S*)-(–)-perillaldehyde, (*R*)-(+)-*p*-menth-1-ene, and (*R,R*)-(+)-*p*-menth-1-en-9-ol, the VCD spectra of the second, third, and fourth overtones of the C–H stretching vibration have been published. The observed couplets can be attributed to a coupled vibration of the $CH_2CH_2C^*H$ fragment.

Other terpenes studied subsequently in the mid-IR include nopinone and (–)-borneol, and a detailed study has focused on the conformers of (+)-menthol [24].

Carbohydrates

Sugars are very good candidates for the measurement of VCD as the more common ECD is dependent on a chromophore, which is almost always absent in this class of natural compounds. The examination of the VCD spectra of six common sugars revealed a chirality rule for the 1150 cm^{-1} band in deuterated dimethyl sulfoxide. Later, the FT-VCD spectra of the carbohydrates D-fucoses, D-arabinose, D-ribose, D-galactose, and D-glucose [25] and their isotopomers deuterated at the hydroxyl groups were examined in the same solvent. Some useful correlations between structure and spectra are

found, but also some deviations.

Cyclodextrins are water-soluble cyclic oligomers of glucose, the most common of which are α -, β -, and γ -cyclodextrin with six, seven, or eight glucose moieties, respectively. Owing to their conical shape with a hydrophobic interior and a hydrophilic exterior, they form water-soluble complexes with inorganic or organic compounds. Comparison of the VCD spectra of the α - and β -cyclodextrins with hydroxyl-deuterated α -cyclodextrin, cyclodextrin-copper complexes, and cyclodextrin inclusion complexes with methyl orange, methyloxirane, *n*-propanol, and substituted cyclohexanones sensitively monitors structural changes in dimethyl sulfoxide- d_6 .

Alkaloids

The spectrum of calycanthin in the C–H and N–H stretching regions can be interpreted as due to the coupling of the chromophore with the substituents. This is in contrast to the common coupling of the two chromophores in chiral dimers, which is commonly used to explain the electronic CD.

VCD investigation of a CCl_4 solution of (–)-sparteine [26] – the alkaloid from lupin beans – and comparison of the experimental results with calculations using EXC theory gave adequate agreement for such a large molecule.

Vibrational CD in the O–H and N–H stretching bands of the anticancer chemotherapeutic agent taxol and two of its side-chain derivatives has been measured and compared with calculations on taxol fragments.

Steroids and Their Precursors

The simple coupled oscillator model, which can readily be applied to large molecules with two identical oscillators, originates from electronic CD. An example of the applicability of the model is given by steroids carrying two

carbonyl functionalities. Even this simple model gives good results for the closely related steroids 3,6-dioxo-5 α -cholestane [27], 3,6-dioxo-5 β -cholic acid methyl ester, 3,7-dioxo-5 β -cholic acid methyl ester, 7,12-dioxo-5 β -cholic acid, 3 α -hydroxy-7,12-dioxo-5 β -cholic acid, and 3-oxo-5 β -cholic acid with only one exception (the 3,7-dioxo derivative).

(+)-5,6,7,8-Tetrahydro-8-methylindane-1,5-dione [28] is an important precursor in the synthesis of estrone. The signs of its experimental VCD spectrum in the 1400–850 cm^{-1} region can be reproduced adequately even using the small basis set 6–31 G. In a later paper, the spectra of the target molecule, estrone [29], were calculated with larger basis sets using HF and DFT methods.

Amino Acids

The simplest amino acid studied is (*S*)-(–)-glycine- $\text{C}_\alpha\text{-}d_1$ [30]. Its weak VCD in the methine stretching region at 2990 cm^{-1} was studied together with those of L-alanine and L-proline, which in contrast to [30] show a positive effect.

Nineteen different amino acids were examined using the C–H stretching vibrational region. Aided by these

Figure 3 Ring current mechanism (positive VCD) in the C–H stretching vibration of an L-amino acid. Redrawn from Freedman TB, Balukjian GA, and Nafie LA (1985) Enhanced vibrational circular dichroism via vibrationally generated electronic ring currents. *Journal of the American Chemical Society* 107: 6213–6222.

VCD spectra, shown explicitly only for L-valine- N - d_3 , a chirality rule was deduced for the chiral methine. If it is supposed that the amino acids are studied form an intramolecular ring in aqueous solution, the VCD of the C^*H stretching vibration will be enhanced so much by ring currents (**Figure 3**) that it will obscure all other vibrations in this region. A positive effect with a value of more than $10^{-4} \text{ cm}^{-1} \text{ mol}^{-1}$ then indicates an L-amino acid.

The vibrational CD spectra of some L-amino acids have been recorded as a function of pH. A large positive bias has been found for the C–H stretching region at neutral or high pH, whereas at low pH the bias is absent and only very small VCD signals are observed. Again the large bias was attributed to ring currents that are possible in some conformations. Another study examined alanine and its deuterated isotopomers.

Seven N -acyl- N' -alkylamide derivatives of different amino acids were measured in CCl_4 and CHCl_3 using the spectral region $3600\text{--}3200 \text{ cm}^{-1}$. The local conformation of the amide moiety was determined as well as the hydrogen bridge bonds using the VCD spectra. Other derivatives studied include N - t -BOC-alanine and N - t -BOC-proline (BOC = butoxy-carbonyl).

Peptides and Proteins

The determination of absolute configuration is not of importance in the study of peptides and proteins. Among the peptides that have been studied are polyalanines, polyprolines, polylysines, polytyrosines, and poly(γ -benzyl-L-glutamate), as well as gramicidin S and other cyclic peptides; proteins examined include α -chymotrypsin, cytochrome c , haemoglobin, myoglobin, ribonuclease S, and triose-phosphate isomerase. VCD spectroscopy is applied with advantage to access the secondary and tertiary structures of these biopolymers. Only a few typical examples are given here from studies published during the 1990s.

Using *ab initio* calculations of the model dipeptide $\text{CH}_3\text{--CONH--CH}_2\text{--CONH--CH}_3$, the VCD of the four most common secondary structures of proteins were calculated and compared successfully with experimental

spectra of albumin, concanavalin A, $(\text{Aib})_2\text{Leu}(\text{Aib})_5$, and poly(L-lysine) (with Aib = α -amino isobutyric acid). The main structure of these proteins is the α -helical, β -sheet, 3_{10} -helical, and poly(L-proline)II conformation.

The favored screw sense of homo-oligopeptides of α -methylated phenylalanine and isovaline has been studied using $p\text{-BrBz-[D-(}\alpha\text{Me)Phe]}_{4,5}\text{-OBU}^t$ [31] and $p\text{-BrBz-[D-Iva]}_5\text{-OBU}^t$ [32] in CDCl_3 solution. Analysis of their VCD spectra shows that the first two compounds are folded in a right-handed 3_{10} -helix, whereas the last pentapeptide forms a left-handed helix.

The calcium-binding milk protein α -lactalbumin and lysozyme from hen egg white show very different VCD spectra, though X-ray analysis reveals that the three-dimensional structures in the crystalline state are very similar. If one adds propanol to an aqueous solution of α -lactalbumin, the helical regions become enlarged and the spectra become similar.

Nucleotides and Nucleic Acids

Base-sequence-characteristic bands have been found in the VCD spectra of six different octadeoxynucleotides in buffered D_2O . These bands belong to the C=O and C--C stretching regions and do not have a counterpart in the absorption spectrum.

Polyribonucleic acids can be measured in aqueous solution using the windows at $1750\text{--}1550 \text{ cm}^{-1}$. In contrast to the monomers, which do not show VCD in this region, the dimers and higher polymers show bisignate VCD bands. The spectra have been calculated for the dimers ApA and CpC, using the coupled oscillator model.

Other Compounds

A study on the pharmaceutically applied ephedrine and pseudoephedrine derived valuable stereochemical information from the VCD spectra.

The model β -lactams 3-methyl- and 4-methylazetidine-2-one [33] readily form dimers in solution, as was clearly observed from the experimental VCD spectra and corresponding *ab initio* calculations.

[33]

A very interesting field of research in the biological area is the chemistry of pheromones. These chemicals strongly attract animals of the same species but of

opposite sex. Stereochemistry is essential for the effectiveness of these substances. As pheromones are often applied in the struggle against insect pests, methods are needed to test the chirality of the natural and synthetic pheromones. For frontalin [34] the pheromone of the southern pine beetle (*Dendroctonus frontalis*), the VCD and absorption spectra of two different conformers have been calculated and compared with the experimental spectrum (Figure 4). In conformation *a*, the six-membered ring is in the chair conformation, whereas in conformation *b*, it is in the boat conformation. The (1*R*,5*S*) configuration and the energetically more stable *a* conformation were assigned to the (+)-isomer on this basis.

The high quality of the VCD calculations feasible nowadays with commercial software can be further

Figure 4 Experimental (in CCl_4) and theoretical (*ab initio* DFT, B3LYP/6-31G*) spectra of (1*R*, 5*S*)-(+)-frontalin: (a) absorption spectra, (b) VCD spectra. Reprinted with permission from Ashvar CS, Stephens PJ, Eggimann T, and Wieser H (1998) Vibrational circular dichroism spectroscopy of chiral pheromones: Frontalin (1,5-dimethyl-6,8-dioxabicyclo[3.2.1]octane). *Tetrahedron: Asymmetry* 9: 1107–1110. © 1998 Elsevier Science B.V.

visualized by two other investigations. Using density functional theory with B3LYP functional, the VCD spectra of the conformers of the small terpene molecule (*S*)-(+)-carvone (*p*-mentha-6,8-dien-2-one, [22]) as well as those of the mitotic inhibitor paclitaxel and baccatin III could be reproduced with such high accuracy that the conformational composition in liquid-state or solution respectively could be deduced.

[34]

Synthetic Polymers

Depending on the method of polymerization, a synthetic chiral polymer can be obtained from methyl methacrylate that has more or less extended isotactic regions. The VCD spectrum of the compounds is substantially more sensitive to its stereochemistry than is the normal IR spectrum.

Menthyl vinyl ether polymers of the diastereomeric menthols (+)-menthol, (+)-isomenthol, and (+)-neomenthol have been synthesized and studied. While the menthyl and the neomenthyl derivatives both showed enhanced VCD features compared to the corresponding monomer, the VCD of the isomethyl derivative was found to stay virtually the same. Poly(menthyl vinyl ether) was studied in greater detail in later work.

Other Applications

Magnetic VCD

If an achiral substance is put into a strong magnetic field, a VCD spectrum can be taken. Important information about molecules, such as the *g* value, can be obtained in this way.

Chiral Detection

A very sensitive detector using the VCD of the O–H stretching vibration can be constructed using a solid-state laser that is circularly polarized by a photoelastic modulator. Using this, 2,2,2-trifluoro-1-(9-anthryl)ethanol and benzoin have been separated on the microgram scale by column chromatography on a chiral stationary phase.

Kinetics

The signal-to-noise ratio of modern VCD spectrometers is now high enough to allow them to follow the course of

a chemical reaction involving chiral molecules. Thus, the ratio of isomerization to stereomutation of 1.4 ± 0.4 at 420°C was derived from study of the thermolysis of (1*R*,2*R*)-1-2-dideuteriocyclobutane, and the reaction constants of the racemization and isomerization of (2*S*,3*S*)-cyclopropane-1-¹³C-1,2,3-*d*₃ were obtained at 407.0°C.

ν	wavenumber frequency
τ	time constant of lock-in amplifier

Introduction

Vibrational circular dichroism (VCD) is defined as circular dichroism (CD) in vibrational transitions in molecules. These transitions typically occur in the infrared (IR) region of the spectrum and hence a VCD spectrometer is an infrared spectrometer that can measure the circular dichroism associated with infrared vibrational absorption bands. CD is defined as the difference in the absorption of a sample for left versus right circularly polarized radiation. This difference is zero unless the sample possesses molecular chirality, either through its constituent chiral molecules or through a chiral spatial arrangement of non-chiral molecules.

A molecule, or an arrangement of molecules, is chiral if it is not superimposable on its mirror image. A chiral molecule possesses a handedness and can exist in either one form, an enantiomer, or its mirror image, the opposite enantiomer. A sample of chiral molecules can have varying chiral purity, referred to as enantiomeric excess. The percent enantiomeric excess (%ee) is defined as the percent excess of one enantiomer relative to the total sample. The %ee of a pure sample of only one enantiomer is 100%. If a sample is composed of an equal mixture of both enantiomers, the %ee is 0% and the sample is called racemic. Racemic samples of chiral molecules exhibit no CD spectra, or any other form of natural optical activity.

The first measurements of VCD were achieved in 1975. The early instruments used for these measurements were relatively crude by today's standards, but they demonstrated that VCD was a natural phenomenon that could be used to study in more detail the structure and dynamics of

chiral molecules. Subsequent improvements in VCD spectrometers included extending the wavelength of coverage from the region of hydrogen-stretching modes into the mid-infrared region where a greater variety of vibrational transitions could be studied. It also included the implementation of Fourier-transform (FT) methods for VCD measurement. This was a particularly important advance, since virtually all modern, commercially available infrared absorption spectrometers are now FT-IR spectrometers. With the advent of FT-VCD, it became possible to construct an efficient VCD spectrometer starting from a commercially available FT-IR spectrometer.

Within the past few years, accessory modules for the measurement of FT-VCD have become available from the manufacturers of several FT-IR spectrometers. In one case, that of the Bomem Chiralix, the first stand-alone, factory-designed FT-VCD spectrometer has become commercially available, opening the way for widespread applications of VCD spectroscopy.

The principal applications of VCD spectroscopy include measurements of the conformation, absolute configuration and enantiomeric excess of chiral molecules. Most of the molecules of interest for study with VCD are biological in origin. Many are molecules of pharmaceutical interest. The unique application of VCD is its ability to determine absolute configuration in conjunction with *ab initio* calculations. Remarkably close matches have been achieved between experimental VCD spectra and the corresponding spectra calculated from first principles using quantum-mechanical calculations.

General Measurement Principles

The measurement of VCD is quite simple in concept. A sample is placed in the VCD spectrometer and the polarization of the IR radiation passing through the sample is switched between left and right circularly polarized states. If the sample is chiral, a small difference in the intensity of the IR beam for left and right circularly polarized IR radiation occurs and is measured at the detector. **Figure 1** illustrates the definition of VCD with an energy-level diagram for molecular transitions between the zeroth and first vibrational sublevels of the ground electronic state, g_0 and g_1 . The decadic absorbance, or IR intensity, of the sample for wavenumber frequency $\bar{\nu}$ (equal to the

frequency of the radiation divided by the speed of light) is defined as

$$A(\tilde{\nu}) = -\log_{10}[I(\tilde{\nu})/I_0(\tilde{\nu})] \quad [1]$$

where $I(\tilde{\nu})$ and $I_0(\tilde{\nu})$ are the single-beam intensities at the detector with and without the sample present, respectively. The circular-polarization differential absorbance, or VCD intensity, is defined as

$$\Delta A(\tilde{\nu}) = A_L(\tilde{\nu}) - A_R(\tilde{\nu}) \quad [2]$$

The basic measurement layout is illustrated in **Figure 2**. Here radiation from an IR source is dispersed either by a diffraction grating or by a Fourier-transform interferometer so that different wavelengths of the radiation can be distinguished. An infrared optical filter is placed in the beam to restrict the measurement to the spectral region of interest. This is followed by a linear polarizer to define a single state of polarization of the infrared beam. A photoelastic

Figure 1 Energy-level diagram illustrating the definition of VCD as the difference in the absorbance of a molecule for left *versus* right circularly polarized IR radiation in a vibrational transition between states g_0 and g_1 in the ground electronic state.

modulator (PEM) then modulates the polarization state of the beam between left (L) and right (R) circularly polarized states at a frequency in the tens of kilohertz range. Immediately afterwards, the sample is placed in the beam. The VCD of the sample creates an intensity modulation of the IR beam at the polarization-modulation frequency. The radiation is then focused on a detector after which further manipulations are carried out electronically to produce the final VCD spectrum. The detector signal is first amplified using a pre-amplifier and then divided into two pathways. One leads directly to the IR spectrum as in an ordinary infrared spectrometer. The other pathway is to a lock-in amplifier, referenced to the PEM, that demodulates the high-frequency polarization-modulation component of the signal and leads to the VCD spectrum as described in more detail below.

The precise way in which the detector signal is processed electronically depends on the kind of VCD spectrometer used. In the following sections, three different VCD spectrometer designs are discussed. The simplest of these is the dispersive VCD spectrometer, and we will use this design to illustrate the basic concepts associated with the electronic processing of VCD spectra. The two subsequent cases involving Fourier-transform VCD spectrometers are more complex, but share the same underlying conceptual basis as the dispersive VCD spectrometer.

Dispersive VCD Spectrometers

In a dispersive VCD spectrometer, the IR source in **Figure 2** consists of a thermal or arc source of infrared radiation, a light chopper and a grating monochromator. The infrared source of radiation is first focused on the entrance slit of the

Figure 2 Diagram illustrating the basic optical layout and electronic pathways for the measurement of VCD. The diagram is applicable to both dispersive VCD spectrometers and FT-IR spectrometers that use a photoelastic modulator (PEM) as the source of the polarization modulation of the light beam between left (L) and right (R) circular states.

monochromator where it is spatially dispersed by the grating. A narrow band of wavelengths (wavenumber frequencies) emerges from the exit slit of the monochromator, and the spectrum is collected by turning the grating and scanning each point in the spectrum sequentially. Successive scans of the monochromator can be averaged to improve the signal-to-noise ratio.

The signal from the detector consists of two components. One is referred to as I_{DC} , which represents the IR single-beam transmission of the sample. In a dispersive VCD spectrometer, I_{DC} is modulated at the frequency of the light chopper and carries the information needed for the ordinary IR spectrum as indicated in **Figure 2**. The other component is I_{AC} , and it is modulated at the polarization-modulation frequency of the PEM, as well as the frequency of the light chopper. In terms of the transmission intensities at the detector for left and right circularly polarized radiation, I_L and I_R , these two components of the detector signal are given by

$$I_{DC}(\bar{\nu}) = (1/2)[I_R(\bar{\nu}) + I_L(\bar{\nu})] \quad [3]$$

$$I_{AC}(\bar{\nu}) = (1/2)[I_R(\bar{\nu}) - I_L(\bar{\nu})]\sin \alpha_M(\bar{\nu}) \quad [4]$$

where I_{AC} depends on the sine of the retardation angle of the PEM, which in turn varies sinusoidally at the PEM frequency $\bar{\nu}_M$:

$$\alpha_M(\bar{\nu}) = \alpha_M^0(\bar{\nu})\sin 2\pi\nu_M t \quad [5]$$

After some algebra, it can be shown that the ratio of the two intensity components in eqns [3] and [4] is proportional to the VCD intensity as

$$I_{AC}(\bar{\nu})/I_{DC}(\bar{\nu}) = 2J_1[\alpha_M^0(\bar{\nu})]1.15\Delta A(\bar{\nu}) \quad [6]$$

where $J_1[\alpha_M^0(\bar{\nu})]$ is the first-order Bessel function and is a measure of the efficiency of the PEM setting for the wavenumber frequency specified.

In order to calibrate VCD measurements, one substitutes the sample with a multiple waveplate followed by a linear polarizer. The fast and slow axes of the multiple waveplate are aligned with the axes of the PEM, and the polarizer is set at 45 degrees from these axes. There are four positions of the multiple waveplate and the polarizer relative to the PEM, and these generate a family of four calibration curves. It can be shown that the intersections of these pseudo-VCD curves have the values

$$[I_{AC}(\bar{\nu})/I_{DC}(\bar{\nu})]_{CAL} = \pm 2J_1[\alpha_M^0(\bar{\nu})] \quad [7]$$

Connecting all the positive intersection points, one obtains a spectral curve, which when divided into eqn [6] allows the isolation of the calibrated VCD intensity spectrum $\Delta A(\bar{\nu})$.

Examples of dispersive VCD and IR spectra for three closely related chiral molecules are presented in **Figure 3**. These spectra are illustrative of a number of basic concepts. All three sets of spectra are recorded in the region of

carbon–hydrogen stretching vibrations. The VCD instrument was constructed in our laboratory at Syracuse University starting in 1975 and optimized over the years to include various kinds of improvements including computer control for automatic operation and signal averaging. The source used was a xenon arc lamp and the detector was a liquid-nitrogen-cooled InSb detector, used for higher-frequency vibrations above 2000 cm^{-1} . The intensity scale is in molar absorptivity in units of $\text{M}^{-1}\text{ cm}^{-1}$ where the absorbance has been divided by the concentration in moles per litre and the pathlength in centimetre. The magnitudes of the VCD spectra are approximately four orders of magnitude smaller than the IR absorbance spectra. The VCD spectra all have a bias towards positive VCD intensity. The source of this bias is demonstrated by the series of three spectra, and it is shown to be the lone methine CH stretching mode. In **Figure 3a**, for (*S*)-methyl-*d*₃ lactate, four CH fundamental modes are present, two for the antisymmetric methyl stretching modes near 3000 cm^{-1} , one for the symmetric methyl stretching mode, with an additional Fermi component at lower frequency, near 2940 cm^{-1} , and the lone methine stretch near 2880 cm^{-1} . Converting this molecule to the deuteriomethoxy analogue, (*S*)-methyl-*d*₃ 2-(methoxy-*d*₃)-propionate, further enhances the lone methine stretching mode relative to the methyl modes as shown in **Figure 3b**. The interfering methyl group is eliminated in the case of **Figure 3c** for di(methyl-*d*₃) D-tartrate where the VCD of the methine can be observed free of other fundamental vibrational modes. The sign of the methine VCD is a marker for the absolute configuration of these and related molecules. The magnitude of the methine VCD is sensitive to the conformation of the molecule in the vicinity of the chiral centre, which for these relatively small molecules is essentially the whole molecule.

Although dispersive VCD spectrometers were the original kind of VCD instrument, they still retain some advantages over the newer Fourier-transform instruments. A relative advantage is present if only a limited spectral range is of interest. In that case a strong source and a narrow filter permit transmission intensities that are higher than could be maintained over a broader spectrum without saturating the detector.

Fourier-Transform VCD Spectrometers

The first measurements of VCD using a Fourier-transform (FT-IR) spectrometer were published in 1979. The basic idea is to substitute the combination of light chopper and monochromator with an FT-IR spectrometer. In an FT-IR spectrometer, all wavelengths of the spectrum of interest are measured at once. The frequencies are distinguished from one another by the interferometer at the heart of the instrument. The infrared light from the source is divided in

Figure 3 Dispersive IR (lower) and VCD (upper) spectra in the region of CH stretching vibrations for the molecules (a) (*S*)-methyl- d_3 lactate, (b) (*S*)-methyl- d_3 2-(methoxy- d_3)-propionate, and (c) di(methyl- d_3) *D*-tartrate illustrating the large positive VCD associated with the methine CH stretching mode in these molecules. The experimental conditions were 0.005 M or 0.01 M solutions in CCl_4 in a 1.00 cm fixed-pathlength cell. The resolution of the VCD spectra is 16 cm^{-1} and of the IR spectra is 4 cm^{-1} .

amplitude at a beamsplitter where one beam is sent to a fixed mirror and the other to a mirror that can change position. The two beams recombine at the beamsplitter and interfere with one another depending on the phase difference of the two light paths. Shorter wavelengths go in and out of phase more rapidly than longer wavelengths and, hence, the different wavelengths can be distinguished from one another by their interference rate or Fourier frequency. The Fourier interference frequency is analogous to the light chopper in the dispersive VCD instrument, but in the case of an FT-VCD instrument, each wavelength has its own 'chopper' frequency. No other changes are needed in the optical setup of the FT-VCD instrument, and hence **Figure 2** is applicable to this instrumental layout as well as that of the dispersive VCD instrument.

The intensity measured by the detector as a function of the moving mirror position, δ , is called an interferogram. The interferogram is a sum of all the intensities of the spectrum at each wavenumber frequency times their Fourier amplitude. Again, there are two intensity components at the detector. One is the ordinary interferogram associated with the single-beam transmission spectrum, and the other is the VCD interferogram that is modulated at the PEM frequency. These component interferograms are given by

$$I_{\text{DC}}(\delta) = \int_0^\infty I_{\text{DC}}(\bar{\nu}) \cos[2\pi\bar{\nu}\delta - \theta_{\text{DC}}(\bar{\nu})] d\bar{\nu} \quad [8]$$

$$I_{\text{AC}}(\delta) = \int_0^\infty I_{\text{AC}}(\bar{\nu}) \exp(-2V\bar{\nu}\tau) \cos[2\pi\bar{\nu}\delta - \theta_{\text{AC}}(\bar{\nu})] d\bar{\nu} \quad [9]$$

where V is the Fourier frequency and τ is the time constant of the PEM lock-in amplifier. The ordinary IR interferogram in eqn [8] contains a phase function, $\theta_{\text{DC}}(\bar{\nu})$, that must be determined before the interferogram can be Fourier transformed to yield $I_{\text{DC}}(\bar{\nu})$. This is evaluated by standard techniques. The VCD interferogram contains its own phase function and this phase is transferred from another VCD interferogram associated with a spectrum of only positive VCD intensities so that standard phase-correction algorithms can be used. Equation [9] also contains an exponential-decay function that decreases with higher wavenumber frequency. This function represents the effect of the time constant of the lock-in amplifier used to demodulate the VCD interferogram from the PEM modulation frequency.

Once eqns [8] and [9] have been Fourier transformed, eqns [6] and [7] can be used to isolate the VCD spectrum although both ratios now also include the exponential function of the lock-in time constant. However, this function vanishes when the calibration curve is divided into the ratio of the AC and DC intensities and does not enter the final VCD spectrum.

An example of an FT-VCD spectrum is presented in **Figure 4**. The IR and VCD spectra of (–)- α -pinene are between 1350 and 850 cm^{-1} . These spectra were measured on the Chiral ir VCD spectrometer from Bomem/Bio-Tools. It employs a SiC glow source and a liquid-nitrogen-cooled HgCdTe (MCT) detector. Again we see the VCD spectrum is displayed on an intensity scale that is

Figure 4 FT-IR (lower) and FT-VCD (upper) spectra of (–)- α -pinene in the mid-IR region. The experimental conditions were neat liquid with a pathlength of 75 μm , a resolution of 4 cm^{-1} and a collection time of 20 min per enantiomer. The final VCD spectrum was obtained from the subtraction of the VCD of the (+)-enantiomer from that of the (–)-enantiomer, as explained in the section on ‘Artifact Suppression’.

approximately four orders of magnitude smaller than the corresponding IR spectrum. Good correspondence is present between the peaks in the IR and VCD spectra, although some overlapping of bands is present. It is easy to see that some VCD bands are positive and some are negative. According to the definition of VCD, the positive bands absorb left circularly polarized light more strongly than right circularly polarized light. There is no particular correlation between strong IR bands and strong VCD bands. The spectrum illustrates the relative strength of FT-VCD to measure spectra over a wide spectral range at high resolution in a relatively short period of time.

A second example of an FT-VCD spectrum is provided in **Figure 5**. The sample in this case is (+)-camphor and the spectral region is the higher-frequency range of CH-stretching vibrations near 3000 cm^{-1} . This spectrum was obtained using a step-scan VCD spectrometer based on an IFS 55 of Bruker Instruments and a VCD accessory bench aligned and optimized in our laboratory at Syracuse University. Step-scan operation offers the advantage of eliminating the decreasing exponential time-constant function associated with the VCD interferogram that disadvantages the higher-frequency region of vibrational transitions. Here a tungsten light source was used in conjunction with an InSb detector. This VCD spectrum is of much higher quality than the corresponding spectrum obtained with a dispersive VCD spectrometer. Step-scan FT-VCD measurements have been carried out as well in the OH and NH stretching regions between 3000 and 3700 cm^{-1} . In some respects collecting a step-scan VCD spectrum is similar to collecting a dispersive VCD spectrum. In each case the spectrum is scanned and averaged a limited number of times, typically two to four times, and a

Figure 5 FT-IR (lower) and step-scan FT-VCD (upper) spectra of R-(+)-camphor in the CH-stretching region. The experimental conditions were a 0.6 M solution in CCl_4 , a pathlength of 43 μm , a resolution of 16 cm^{-1} and a collection time of 2 h per enantiomer. The final VCD spectrum was obtained from the subtraction of the VCD of the (–)-enantiomer from that of the (+)-enantiomer, as explained in the section on ‘Artifact Suppression’.

relatively long time constant can be employed with the PEM lock – since one is not trying to protect a band of Fourier frequencies. The principal difference between the two kinds of measurements is that the light level is not diminished by the reduction of slitwidth if higher resolution is desired, and all the light is used in the FT measurement rather than leaving most of it on the inside of the monochromator as in the case of the dispersive VCD measurement.

Polarization-Division FT-VCD Spectrometers

In 1989, a new kind of FT-VCD measurement was demonstrated, originally called polarization-modulation interferometry (PMI) and more recently called polarization-division interferometry (PDI). In this approach a polarizing beamsplitter is substituted for the normal amplitude-division beamsplitter. If a linearly polarized infrared beam, with a direction of polarization at 45 degrees relative to the polarization direction of the beamsplitter, is directed to this beamsplitter, then the beam is split into two orthogonally polarized beams. Upon recombination at the beamsplitter, the two beams combine but they do not interfere. The result of the movement of the moving mirror associated with one of

the beams is that the polarization state of each wavelength of light cycles continuously through 360 degrees of relative phase retardation at its own Fourier frequency. The cycle starting with vertically polarized radiation is vertical linear, right circular, horizontal linear, left circular and back to vertical linear. In the ideal case, there is no intensity modulation, only polarization modulation. In order to measure a conventional FT-IR absorption spectrum, one can insert a polarizer, say in the vertical position, and the beam is converted from polarization modulation to intensity modulation. Maximum intensity occurs when the beam is vertical linear and minimum when it is horizontal linear. Without the polarizer present, the interferometer is sensitive to linear dichroism in the sample oriented vertically or horizontally at the same Fourier phase as the absorption spectrum (cosine transform) and is sensitive to circular dichroism (VCD) out of phase relative to the absorption spectrum (sine transform). **Figure 6** illustrates the polarization cycles and the mode of operation of this instrument for absorption, linear dichroism and circular dichroism measurements.

The advantage of PDI-FT spectrometers is their independence of PEMs. A PEM has a limited range of wavelength coverage, and there are no PEMs commercially available that operate into the far IR. Yet, there are polarizing beamsplitters that have good efficiency in the far IR, and hence PDI-FT-VCD is the likely approach to extend VCD into this region of the spectrum. To date, the performance of PDI-FT-VCD spectrometers is somewhat below that of PEM-FT-VCD spectrometers in the region where they have been directly compared, the mid-IR region. An FT-VCD instrument has been described that possessed both PDI capability and conventional polarization-modulation capability using a PEM. Referred to as double polarization modulation interferometry, this technique offers advantages of signal intensity compared to other single polarization modulation FT-VCD spectrometers.

Artifact Suppression

VCD intensities are smaller than IR intensities by approximately four orders of magnitude. As a result they are subject to interference from optical imperfections in the instrument itself. The manifestations of these imperfections, which differ from instrument to instrument, are called artifacts. Artifacts arise from the combination of birefringence in the optics and a sensitivity to different states of linear polarization by the detector or by optical reflection surfaces. The birefringence arises from strain in windows and lenses. Birefringence alters the polarization state of the light and disturbs the balance between left and right circularly polarized light in the spectrometer. A PEM is an oscillating birefringent plate and its action

creates the oscillating left and right circular polarization states in the first place. Stray birefringence in the optics, including within the PEMs, further alters the polarization states in undesirable, unknown ways. Once the symmetry between the left and right circular polarization states is broken, the instrument possesses some, perhaps small, degree of linear polarization modulation at the PEM frequency. If the detector or surface of some other optical element responds differentially to the linear polarization modulation, an artifact intensity is created that coexists with the VCD intensity.

There are two kinds of artifacts. One is independent of the sample and exists as a common background spectrum. It can be recorded in the absence of a sample or with any racemic or non-chiral sample, such as a solvent. Once recorded, it may be subtracted automatically from all future VCD spectra to remove this background signal from the measurement. The second kind of artifact is one that varies with the absorption spectrum of the sample or solvent. This is more difficult to remove. In fact, the only way currently known that it can be removed completely from a measurement is by subtraction of the VCD spectrum of the racemic mixture or the opposite enantiomer of the chiral sample. It is important that the racemic or enantiomer VCD measurement be made under the same conditions as the desired chiral measurement, namely, the same pathlength, concentration and cell position. From the standpoint of signal quality, it is more effective to record the VCD spectrum of the opposite enantiomer rather than the racemic mixture since in the former case, the subtraction adds additional VCD information while at the same time cancelling the common artifact spectrum. Unfortunately, a sample of the opposite enantiomer or the racemic mixture is not always available. For this reason, great care needs to be exercised to reduce the occurrence of both kinds of artifacts in the initial optical alignment of the VCD spectrometer.

In practice, it is found that reducing the constant background artifact also reduces the severity of the absorption-dependent artifact. It has also been found that using lenses instead of mirrors after the first polarizer in the optical train can reduce the background artifact. Mirrors possess both birefringence and sensitivity to different states of linear polarization. When used off-axis, as is usually the case, these effects are enhanced on the IR beam. Lenses, on the other hand, can be used on-axis and exhibit lower artifact-inducing effects. In addition to using lenses, the optical alignment should be purely axial and cylindrically symmetric so that a particular direction in space, beyond the direction of beam propagation, is not favoured in the alignment. The final alignment can be achieved by minor adjustment of the optics on a trial and error basis until a good instrument baseline is reached. If the baseline is relatively flat and close to zero across the spectrum, it is usually found that absorption-dependent artifacts are not a serious problem.

$$\text{Absorbance, } A = -\log \frac{I}{I_0}$$

Figure 6 Diagram illustrating the polarization sequence and measurement setups for FT-IR, FT-VCD and FT-VLD with a PDI-FT spectrometer. For absorption measurements, the placement of a vertical polarizer converts the train of polarization modulation to intensity modulation. The polarizer is removed for VCD and VLD measurements as illustrated. Key: VLP, vertical linear polarization; RCP, right handed circular polarization; HLP, horizontal linear polarization; LCP, left handed circular polarization; CD, circular dichroism; LD, linear dichroism.

Absolute VCD Intensity

An important aspect of instrumentation performance is absolute intensity calibration. The intensity-calibration procedure described above using the multiple waveplate and second polarizer has been the method of choice for the calibration of VCD spectra for many years.

Nevertheless, the technique is prone to variation depending on the accuracy and care is taken in the calibration measurement. If the multiple waveplate or the second polarizer is not positioned at the optimum angular orientation, a calibration spectrum is obtained that is not correct. Usually, the calibration spectrum is too small and the resulting calibrated VCD spectrum has

intensities that are too large. Another common source of error is the aperture of the beam used in the calibration measurement relative to that used for the VCD measurement. The degree of polarization modulation in a PEM varies with aperture, decreasing from its centre. The calibration measurement determines the J_1 function of the PEM averaged over the beam profile, and the correct calibration is obtained only if the aperture of the VCD measurement matches the aperture of the calibration measurement.

In an effort to establish an intensity standard for VCD measurements, a number of laboratories have undertaken the measurement of the mid-infrared VCD spectrum of (–)- α -pinene. The results from several laboratories have been obtained to date and the results have been plotted in molar absorptivity units. In **Figure 7**, we present the absolute VCD measurements from three locations. The results are still preliminary, and though they show a variation of the order of 10%, these intensities and others appear to be converging on a particular set of values. It is hoped that a set of accepted values with a small range of uncertainty will be available in the near future. With a set of absolute intensities in hand, the calibration of a VCD spectrometer could then be carried out by comparison with a standard set of spectra rather than by a calibration measurement subject to the operational errors discussed above.

Areas of Application

There are three principal areas of application of VCD spectroscopy. The first, and simplest, is to use VCD

spectra to measure the optical purity in terms of %ee of a sample or series of samples. The second application is to determine the absolute configuration of the molecules in the sample, and the third is to determine the solution-state conformations of molecules present in the sample.

Determination of Enantiomeric Excess

In the case of optical-purity measurements, the determination of %ee is based on the fact that the VCD intensity varies linearly from 100% to 0% with the %ee. The VCD spectrum obtains its maximum value for a chirally pure sample of a single enantiomer; it falls to half its value for a %ee value of 50% and vanishes for the racemic solution where the %ee is 0%. This linear relationship is demonstrated in **Figure 8** where the VCD spectra of (–)- α -pinene for three different values of %ee are plotted for the region from 1150 to 1075 cm^{-1} . Here it is clear that the VCD in both bands decreases in value as the %ee is lowered from 100% to 95% to 90%. A partial least-squares analysis of the entire VCD spectrum of (–)- α -pinene from 1350 to 900 cm^{-1} for a wide range of %ee values leads to a degree of precision in predicting the %ee from the VCD spectrum of better than 1%. Similar accuracies have been achieved for other molecules. The only prior requirement for the determination of %ee is a high-quality VCD reference spectrum of a sample with known optical purity. From such a VCD spectrum, the VCD intensities for a pure sample at 100 %ee can be determined and all subsequent unknowns can be referenced to this measurement.

Figure 7 Measurements of the VCD spectrum of neat (–)- α -pinene from three different laboratories illustrating both the variation that can arise in the measurement of absolute intensities and the convergence of the measurements to a relatively narrow range of values.

Figure 8 Three VCD spectra of (–)- α -pinene for decreasing values of optical purity, 100%, 95% and 90% enantiomeric excess. The experimental conditions were 70 μm pathlength, 8 cm^{-1} resolution and 2 h of collection time for each sample.

There are several advantages of VCD for the determination of optical purity that are not available in the more traditional methods. First, compared to the measurement of optical rotation, VCD intensity can usually be observed in most molecules at approximately the same level of intensity for the strongest bands in the spectrum. This intensity is approximately four orders of magnitude smaller than the IR absorbance spectrum. On the other hand, values of optical rotation can vary widely.

VCD intensities are not temperature sensitive. VCD spectra are composed of many bands and many spectral points, each one of which is a determinant of the %ee relative to the same point in another sample. Averaging over all the points in the spectrum weighted by their importance to the spectrum, leads to an accurate overall determination. By contrast, optical rotation is a single, temperature-sensitive measurement. The multi-spectral aspect of VCD allows accurate results to be obtained even if there is more noise in a VCD spectrum than in a single optical-rotation measurement.

Compared to chiral chromatography, VCD spectra can be obtained without a physical separation of the two enantiomers. In some cases, enantiomeric pairs of molecules cannot be separated sufficiently with a column, and in this case VCD can be useful. Chiral columns are also expensive to develop and operate, and VCD can be used for routine measurement in a time that is less than that usually required for a physical separation and optical-purity measurement.

The prospects are bright for further improvements of VCD to determine the optical purity of samples. The use of VCD for this purpose is still in an early stage of development, and it is likely that improved measurement and analysis techniques will increase the accuracy of VCD %ee determinations to well below 1% for most samples.

Determination of Absolute Configuration

A powerful application of VCD is the determination of the absolute configuration of chiral molecules. VCD is more effective than electronic CD (ECD) in this respect for at least two reasons. One is the number of transitions and the richness of a VCD spectrum compared to an ECD spectrum. There are many more possible transitions to consider in looking for ways to connect the CD spectrum to the absolute configuration. The second reason is that it is easier to calculate IR absorption and VCD spectra than it is to calculate UV absorption and ECD spectra. The latter require accurate descriptions of excited electronic state wavefunctions, whereas a vibrational spectrum can be calculated only on the basis of the ground electronic state and its response to nuclear motion. This information is readily available when the equilibrium ground-state geometry is optimized and its molecular force field is determined.

There is widespread interest in the capability of VCD to determine absolute configurations of molecules because the method is free of the need to obtain a single crystal for X-ray diffraction measurements, the standard approach to the determination of absolute configuration of a chiral molecule. VCD measurements are typically carried out in solution or with neat liquids. Since many molecules are difficult to crystallize, VCD promises to be an effective way to determine stereo-specific structures in the absence of the availability of crystals.

Over the past several years, several laboratories have demonstrated that the absolute configuration of a molecule can be determined *de novo* without reference to any other measurement or information base. The method involves carrying out an *ab initio* calculation of the VCD of a particular enantiomer of the chiral molecule. This serves as a theoretical prediction of its VCD spectrum. Next, the VCD spectrum of the molecule is measured and compared to the theoretical prediction. If the sign pattern agrees, the absolute configuration is confirmed to be the one calculated. If the signs are opposite, then the absolute configuration of the molecule in the sample is opposite to the configuration used in the calculation.

An example of the determination of absolute configuration is shown in **Figure 9**. Here the FT-VCD spectrum of (*S*)-methyl lactate in the mid-infrared region is compared to the corresponding *ab initio* calculation using density-functional theory (DFT) and magnetic-field perturbation (MFP) at the 6-31G* basis set level. There are no adjustable parameters to the calculation, and the calculated intensities have been plotted using band shapes similar to the experimentally measured IR and VCD spectra. There is excellent agreement in sign and intensity for both the VCD and IR spectra and there is no doubt that the experimental spectrum was the *S*-enantiomer of this molecule and not the *R*-enantiomer. The theoretical

Figure 9 Comparison of the experimental and theoretical IR (lower) and VCD (upper) spectra of (*S*)-methyl lactate. The calculation was carried out using density-functional theory and the magnetic-field perturbation theory of VCD intensities. No adjustable parameters were used for the theoretical calculation other than choosing the bandshape for the vibrational transitions.

programs used to carry out these calculations are available commercially with the Gaussian 98 set of quantum-chemistry programs.

In addition to this powerful approach to the determination of absolute configuration by VCD, it is also possible to gain information about the absolute configuration of members of a family of structurally related molecules by empirical correlation. Among the many bands present in a VCD spectrum, there are often one or more that serve as reliable markers of absolute configuration for a particular chiral centre. One of the best known examples, illustrated in **Figure 3**, is the methine CH stretch of amino acids and hydroxy acids. The *S*-enantiomer (*L*-amino acid) always exhibits a positive VCD band for reasons that are currently being explored using detailed quantum-chemistry calculations. Other examples of markers of absolute configuration abound, and such markers can typically be found for any set of structurally related molecules.

Stereo-Conformational Analysis

The final area of the application of VCD spectroscopy to be discussed here is stereo-conformational analysis. This is the most sophisticated level of VCD application. Here

one is concerned about determining the conformation of chiral molecules in solution. This is the principal research application of VCD, and VCD has been used for this purpose for many years. Nearly all classes of chiral molecules have been explored using VCD. Most of these are molecules of biological significance such as amino acids, peptides, sugars, proteins, nucleic acids and most classes of pharmaceutical molecules. Many excellent reviews have been written on the application of VCD to the study of these molecules. Most recently it has been demonstrated that quantum calculations can be used to determine the presence and relative population of various solution-state conformers of chiral molecules. Theoretically predicted VCD spectra of the most stable conformers of the chiral molecule are compared to the experimental VCD spectrum. A best fit is then sought starting from a Boltzmann distribution of the theoretically determined spectra. Deviations from the VCD spectrum predicted by the Boltzmann distribution are explained in terms of the influence of the solvent on the stability of the various conformers. In this way, new information is obtained about the solution-state structures that are present under particular conditions of solvent, temperature and concentration.

Future Performance

The design and performance of VCD spectrometers have advanced dramatically since the first measurements of VCD. Commercial VCD instruments have been available since the turn of the millennium, and improvements are continuing to enhance the utility of the technique such that it is becoming a mainstream approach for stereo-chemical investigations.

Introduction

Circular dichroism (CD) can be observed in the vibrational transitions of chiral molecules: vibrational circular dichroism (VCD). An example of a VCD spectrum is shown in **Figure 1**, together with the corresponding unpolarized absorption spectrum. The sample is a 0.6 M solution of (1R,4R)-(+)-camphor in CCl₄. Here, we discuss the theoretical analysis of VCD spectra. The current state-of-the-art is illustrated in **Figure 1**, where VCD and absorption spectra of camphor, predicted within the harmonic approximation (HA) using *ab initio* density functional theory (DFT), are shown.

Theory

We restrict our discussion to the case of isotropic dilute solutions of randomly oriented molecules, e.g. liquid

solutions or amorphous solid solutions. (In practice, the vast majority of VCD experiments are carried out using liquids at room temperature.) Beer's Law applies:

$$A = \varepsilon c l \quad [1]$$

$$\Delta A \equiv A_L - A_R = (\varepsilon_L - \varepsilon_R) c l \equiv (\Delta \varepsilon) c l \quad [2]$$

where A = absorbance, L and R denote left and right circularly polarized light, ΔA = circular dichroism, ε = molar extinction coefficient, c = concentration (mol L⁻¹) and l = pathlength (cm). The unpolarized absorption is

$$A \equiv \frac{1}{2}(A_L + A_R) = \frac{1}{2}(\varepsilon_L + \varepsilon_R) c l \equiv \bar{\varepsilon} c l \quad [3]$$

Semi-classical treatment of the interaction of molecules with electromagnetic waves leads to equations for ε and $\Delta \varepsilon$ in terms of molecular properties:

$$\bar{\varepsilon}(\nu) = \frac{8\pi^3 N \nu}{(2.303) 3000 bc} \sum_{g,k} \alpha_g D_{gk} f_{gk}(\nu_{gk}, \nu) \quad [4]$$

$$\Delta \varepsilon(\nu) = \frac{32\pi^3 N \nu}{(2.303) 3000 bc} \sum_{g,k} \alpha_g R_{gk} f_{gk}(\nu_{gk}, \nu) \quad [5]$$

$$D_{gk} = |\langle g | \mu_{el} | k \rangle|^2 \quad [6]$$

$$R_{gk} = \text{Im}[\langle g | \mu_{el} | k \rangle \bullet \langle k | \mu_{mag} | g \rangle] \quad [7]$$

where $g \rightarrow k$ is a molecular excitation of frequency ν_{gk} , α_g is the fraction of molecules in state g , and $f(\nu_{gk}, \nu)$ is a normalized line shape function (e.g. Lorentzian). D_{gk} and R_{gk} are the dipole strength and rotational strength of the excitation $g \rightarrow k$. μ_{el} and μ_{mag} are the electric and magnetic dipole moment operators:

$$\mu_{el} = - \sum_i e r_i + \sum_{\lambda} (Z_{\lambda} e) R_{\lambda} \equiv \mu_{el}^e + \mu_{el}^n \quad [8]$$

$$\mu_{mag} = - \sum_i \frac{e}{2mc} (r_i \times p_i) + \sum_{\lambda} \left(\frac{Z_{\lambda} e}{2M_{\lambda} c} \right) \times (R_{\lambda} \times P_{\lambda}) \equiv \mu_{mag}^e + \mu_{mag}^n \quad [9]$$

Here, $-e$ and $Z_{\lambda}e$, r_i , and R_{λ} , p_i and P_{λ} are the charge, position and momentum of electron i and nucleus λ

Figure 1 Experimental (a, c) and calculated (b, d) absorption (a, b) and VCD (c, d) spectra of (1*R*, 4*R*)-(+)-camphor. The resolution of the experimental spectra was 4 cm⁻¹. Calculated spectra were obtained using DFT, B3PW91 and 6-31G*. Band shapes are Lorentzian (half width at half height 4 cm⁻¹). Fundamental modes are numbered.

respectively. Equations [4] and [5] do not include the effects of the condensed-phase medium either on the molecular properties α_g , D_{gb} , R_{gk} and v_{gk} or on the electromagnetic fields of the radiation: ‘solvent effects’.

In the case of vibrational transitions, g and k are vibrational levels of the ground electronic state, G . Within the Born–Oppenheimer (BO) approximation:

$$\Psi_g(\mathbf{r}, \mathbf{R}) = \psi_g(\mathbf{r}, \mathbf{R}) \chi_{Gg}(\mathbf{R}) \quad [10]$$

$$\Psi_k(\mathbf{r}, \mathbf{R}) = \psi_k(\mathbf{r}, \mathbf{R}) \chi_{Gk}(\mathbf{R}) \quad [11]$$

where

$$H_d(\mathbf{r}, \mathbf{R}) \psi_g(\mathbf{r}, \mathbf{R}) = W_G(\mathbf{R}) \psi_g(\mathbf{r}, \mathbf{R}) \quad [12]$$

$$[W_G(\mathbf{R}) + T_n(\mathbf{R})] \chi_{Gv}(\mathbf{R}) = E_v \chi_{Gv}(\mathbf{R}) \quad [13]$$

where $\mathbf{r}$ and $\mathbf{R}$ denote electronic and nuclear coordinates respectively. H_{el} is the adiabatic ‘electronic Hamiltonian’:

$$H_{el} = T_e + V_{ee} + V_{en} + V_{nn} \quad [14]$$

comprising the electronic kinetic energy and the Coulombic interactions of electrons and nuclei. Ψ_G and W_G are the wavefunction and energy of the ground electronic state. χ_{Gv} and E_v are the wavefunction and energy of the vibrational level v arising from vibrational motion on the potential energy surface (PES) $W_G(\mathbf{R})$.

For simplicity, we restrict discussion now by assuming that only the lowest vibrational level is populated and that the PES, W_G , is harmonic:

$$\begin{aligned} W_G &= W_G^0 + \frac{1}{2} \sum_{\lambda\alpha\lambda'\alpha'} \left(\frac{\partial^2 W_G}{\partial X_{\lambda\alpha} \partial X_{\lambda'\alpha'}} \right)_0 X_{\lambda\alpha} X_{\lambda'\alpha'} \\ &= W_G^0 + \frac{1}{2} \sum_i k_i Q_i^2 \end{aligned} \quad [15]$$

where W_G^0 is the energy of G at equilibrium, $\mathbf{R} = \mathbf{R}_0$; $X_{\lambda\alpha}$ is the displacement of nucleus λ ($\lambda = 1 \dots N$) along Cartesian axis α ($\alpha = x, y, z$); Q_i are normal coordinates, simultaneously diagonalizing the nuclear kinetic energy:

$$T_n = \frac{1}{2} \sum_i \dot{Q}_i^2 \quad [16]$$

The force constants, k_i , determine the normal mode frequencies:

$$v_i = \frac{1}{2\pi} \sqrt{k_i} \quad [17]$$

The vibrational states of this harmonic PES are of energy

$$\begin{aligned} E(v_1, v_2 \dots v_{3N}) &= \sum_i (v_i + \frac{1}{2}) h\nu_i \\ (v_i &= 0, 1, 2 \dots) \end{aligned} \quad [18]$$

For six modes, corresponding to translational and rotational motions, k_i and ν_i are zero.

Within the HA, electric dipole transition moments are

$$\begin{aligned} \langle g | \mu_{el} | k \rangle &\equiv \langle \psi_G \chi_{Gg} | \mu_{el} | \psi_G \chi_{Gk} \rangle \\ &= \langle \chi_{Gg} | \langle \psi_G | \mu_{el} | \psi_G \rangle | \chi_{Gk} \rangle \end{aligned} \quad [19]$$

which, on expanding $\langle \psi_G | \mu_{el} | \psi_G \rangle \equiv \mu_{el}^G$

$$\mu_{el}^G = (\mu_{el}^G)_o + \sum_i \left(\frac{\partial \mu_{el}^G}{\partial Q_i} \right)_o Q_i + \dots \quad [20]$$

leads to non-zero transition moments from the vibrational ground state (all $v_i = 0$) only for fundamental transitions involving one mode alone, i.e. to the states $v_i = 1$, $v_j = 0$ ($j \neq i$). The transition moment for the fundamental in mode i is

$$\langle 0 | \mu_{el} | 1 \rangle_i = \left(\frac{\partial \mu_{el}^G}{\partial Q_i} \right)_o \left(\frac{\hbar}{4\pi\nu_i} \right)^{1/2} \quad [21]$$

Equation [21] can be rewritten in terms of derivatives of the molecular electric dipole moment μ_{el}^G , with respect to the Cartesian displacement coordinates, $X_{\lambda\alpha}$. With

$$X_{\lambda\alpha} = \sum_i S_{\lambda\alpha,i} Q_i \quad [22]$$

eqn [21] becomes

$$\langle 0 | (\mu_{el})_\beta | 1 \rangle_i = \left(\frac{\hbar}{4\pi\nu_i} \right)^{1/2} \sum_{\lambda\alpha} S_{\lambda\alpha,i} P_{\alpha\beta}^\lambda \quad [23]$$

where

$$P_{\alpha\beta}^\lambda \equiv \left(\frac{\partial (\mu_{el}^G)_\beta}{\partial X_{\lambda\alpha}} \right)_o \quad [24]$$

The second-rank molecular tensors, $P_{\alpha\beta}^\lambda$, are termed atomic polar tensors (APT). Separating electronic and nuclear parts:

$$\begin{aligned} P_{\alpha\beta}^\lambda &= E_{\alpha\beta}^\lambda + N_{\alpha\beta}^\lambda \\ E_{\alpha\beta}^\lambda &= \left[\frac{\partial}{\partial X_{\lambda\alpha}} \langle \psi_G | (\mu_{el}^e)_\beta | \psi_G \rangle \right]_0 \\ N_{\alpha\beta}^\lambda &= (Z_\lambda e) \delta_{\alpha\beta} \end{aligned} \quad [25]$$

We can further write

$$E_{\alpha\beta}^\lambda = 2 \left\langle \left(\frac{\partial \psi_G}{\partial X_{\lambda\alpha}} \right) | (\mu_{el}^e)_\beta | \psi_G^0 \right\rangle \quad [26]$$

The dipole strength of the fundamental excitation of mode i is then

$$\begin{aligned} D_i &= \left(\frac{\hbar}{4\pi\nu_i} \right) \left| \left[\frac{\partial (\mu_{el}^G)_\beta}{\partial Q_i} \right]_0 \right|^2 \\ &= \left(\frac{\hbar}{4\pi\nu_i} \right) \sum_\beta \sum_{\lambda\alpha\lambda'\alpha'} \left[S_{\lambda\alpha,i} P_{\alpha\beta}^\lambda \right] \left[S_{\lambda'\alpha',i} P_{\alpha'\beta}^{\lambda'} \right] \end{aligned} \quad [27]$$

The formulation of magnetic dipole transition moments is unfortunately less straightforward. Compare the electronic contributions to the electric and magnetic

dipole moments of G :

$$(\boldsymbol{\mu}_{\text{el}}^G)^e = \langle \psi_G | \boldsymbol{\mu}_{\text{el}}^e | \psi_G \rangle \quad [28]$$

$$(\boldsymbol{\mu}_{\text{mag}}^G)^e = \langle \psi_G | \boldsymbol{\mu}_{\text{mag}}^e | \psi_G \rangle \quad [29]$$

Considering only non-degenerate electronic ground states (in practice very few chiral molecules are exceptions) $\boldsymbol{\mu}_{\text{el}}^G$ and $\boldsymbol{\mu}_{\text{mag}}^G$ are qualitatively different because $\langle \Psi_G | \boldsymbol{\mu}_{\text{mag}}^e | \Psi_G \rangle = 0$ at all molecular geometries. That is, electrons make zero contribution to the adiabatic magnetic dipole moment. It follows that, in the case of magnetic dipole transition moments, the BO approximation leads to a non-physical result. The treatment of magnetic dipole transition moments requires more accurate vibronic wavefunctions. The vibrational states g and k must be written

$$\begin{aligned} \Psi_g &= \psi_G \chi_{Gg} + \sum_{E \neq G} (\psi_E \chi_{Eg}) c_{Gg, Ee} \\ \Psi_k &= \psi_G \chi_{Gk} + \sum_{E \neq G} (\psi_E \chi_{Ek}) c_{Gk, Ee} \end{aligned} \quad [30]$$

allowing for the admixture of BO functions of excited electronic states E into the ground state. This in turn permits non-zero vibrational transition moments of $\boldsymbol{\mu}_{\text{mag}}^e$ to be obtained; simply put, electronic magnetic dipole transition moments are ‘stolen’ by mixing of BO states. The reader is referred to the literature for the details. The final result is that

$$\langle 0 | (\boldsymbol{\mu}_{\text{mag}})_\beta | 1 \rangle_i = (4\pi\hbar^3 v_i)^{1/2} \sum_{\lambda\alpha} S_{\lambda\alpha, i} M_{\alpha\beta}^\lambda \quad [31]$$

where

$$\begin{aligned} M_{\alpha\beta}^\lambda &= I_{\alpha\beta}^\lambda + J_{\alpha\beta}^\lambda \\ I_{\alpha\beta}^\lambda &= \left\langle \left(\frac{\partial \psi_G}{\partial X_{\lambda\alpha}} \right)_0 \middle| \left(\frac{\partial \psi_G}{\partial H_\beta} \right)_0 \right\rangle \\ J_{\alpha\beta}^\lambda &= \frac{i}{4\hbar c} \sum_\gamma (Z_\lambda e) R_{\lambda\gamma}^0 \epsilon_{\alpha\beta\gamma} \end{aligned} \quad [32]$$

The tensors $M_{\alpha\beta}^\lambda$ are termed atomic axial tensors (AATs); $I_{\alpha\beta}^\lambda$ and $J_{\alpha\beta}^\lambda$ are the electronic and nuclear components. Here, $(\partial \psi_G / \partial X_{\lambda\alpha})_0$ is the same derivative which occurred already in eqn [26]. The electronic AAT, $I_{\alpha\beta}^\lambda$, is the overlap integral with the derivative $(\partial \psi_G / \partial H_\beta)_0$. This latter is defined via

$$\begin{aligned} H(H_\beta) &= H_{\text{el}} + H'(H_\beta) \\ H'(H_\beta) &= - \left(\boldsymbol{\mu}_{\text{mag}}^e \right)_\beta H_\beta \\ H(H_\beta) \psi_G(H_\beta) &= W_G(H_\beta) \psi_G(H_\beta) \end{aligned} \quad [33]$$

That is: $\psi_G(\mathbf{H})$ is the wavefunction of G in the presence of

a uniform external magnetic field, $\mathbf{H}$, approximating the perturbation by the linear magnetic dipole interaction $H'(\mathbf{H})$.

The rotational strength of the fundamental excitation of mode i is then

$$R_i = \hbar^2 \sum_\beta \sum_{\lambda\alpha, \lambda'\alpha'} [S_{\lambda\alpha, i} P_{\alpha\beta}^\lambda] [S_{\lambda'\alpha', i} M_{\alpha'\beta}^{\lambda'}] \quad [34]$$

Computation

Within the HA, the prediction of a vibrational absorption spectrum amounts to the calculation of the harmonic normal mode frequencies, ν_i , and dipole strengths, D_i . The frequencies are obtained from the harmonic force field (HFF). With respect to Cartesian displacement coordinates, this is the Hessian $(\partial^2 W_G / \partial X_{\lambda\alpha} \partial X_{\lambda'\alpha'})_0$. Diagonalization (after mass-weighting) yields the force constants k_i , the frequencies, ν_i , and the normal coordinates, Q_i i.e. the transformation matrices, $S_{\lambda\alpha, i}$. The dipole strengths depend in addition on the APTs; these require calculation of $(\partial \psi_G / \partial X_{\lambda\alpha})_0$.

The prediction of a VCD spectrum amounts likewise to the calculation of the harmonic frequencies and rotational strengths, R_i . All of the quantities required in predicting the absorption spectrum are again needed; in addition, the AATs must be calculated. Since $(\partial \psi_G / \partial X_{\lambda\alpha})_0$ is already required for the APTs, the AATs require additionally only $(\partial \psi_G / \partial H_\beta)_0$.

In sum: the prediction of both absorption and VCD spectra requires (i) $(\partial^2 W_G / \partial X_{\lambda\alpha} \partial X_{\lambda'\alpha'})_0$; (ii) $(\partial \psi_G / \partial X_{\lambda\alpha})_0$; (iii) $(\partial \psi_G / \partial H_\beta)_0$. The prediction of the VCD spectrum requires relatively little more than is needed for the absorption spectrum: specifically, $(\partial \psi_G / \partial H_\beta)_0$.

The calculation of molecular properties can be carried out at three distinct levels: (i) *ab initio*, (ii) semi-empirical, (iii) empirical. *Ab initio* methods have increased enormously in accuracy and efficiency and are the focus of our discussion here. *Ab initio* methods have developed in two directions: first, the level of approximation has become increasingly sophisticated and, hence, accurate. The earliest *ab initio* calculations used the Hartree-Fock/self-consistent field (HF/SCF) methodology, which is the simplest to implement. Subsequently, such methods as Møller-Plesset perturbation theory, multi-configuration self-consistent field theory (MCSCF) and coupled-cluster theory have been developed and implemented. Relatively recently, density functional theory (DFT) has become very popular, since it yields an accuracy much greater than that of HF/SCF while requiring relatively little additional computational effort.

The second dimension in which *ab initio* theory has progressed is that of derivative techniques. Many molecular properties of interest – including, as shown above,

the HFF, APTs and AATs – can be expressed in terms of derivatives of energies and wavefunctions with respect to perturbations. Such derivatives can be evaluated using either numerical or analytical methods. For example, the energy gradients $(\partial W_G/\partial X_{\lambda\alpha})_0$ can be evaluated either by calculating W_G at $\mathbf{R}_0$ and $\mathbf{R}_0 + X_{\lambda\alpha}$ and using

$$\left(\frac{\partial W_G}{\partial X_{\lambda\alpha}}\right)_0 \approx \frac{W_G(\mathbf{R}_0 + X_{\lambda\alpha}) - W_G(\mathbf{R}_0)}{X_{\lambda\alpha}} \quad [35]$$

or by formulating an equation for $(\partial W_G/\partial X_{\lambda\alpha})_0$ and then carrying out direct evaluation. Similarly, a Hessian matrix can be obtained by finite-differences of gradients or analytically. Analytical derivative methods are much more efficient. Much of the recent expansion in usage of *ab initio* quantum chemistry has resulted from advances in formulating and implementing analytical derivative techniques for an increasing diversity of molecular properties at an increasing number of theoretical levels.

The simultaneous calculation of HFFs, APTs and AATs using analytical derivative *ab initio* methods has been implemented in three program packages: CADPAC, DALTON and GAUSSIAN. The levels of implementation are:

CADPAC	HF/SCF
DALTON	HF/SCF and MCSCF
GAUSSIAN	HF/SCF and DFT.

The accuracies of these methods are:

$$\text{HF/SCF} < \text{MCSCF} \ll \text{DFT}.$$

The computational effort is:

$$\text{HF/SCF} < \text{DFT} \ll \text{MCSCF}.$$

The ratio of accuracy to effort is:

$$\text{DFT} \gg \text{HF/SCF} > \text{MCSCF}.$$

Thus, DFT is currently the most cost-effective methodology available.

An additional variable in *ab initio* calculations is the basis set. Two choices are to be made: (i) perturbation-independent or perturbation-dependent; (ii) size and composition. In calculating derivatives with respect to nuclear displacements, $X_{\lambda\alpha}$, one can adopt basis functions which either (a) are not or (b) are functions of nuclear position. The latter add computational complexity but vastly improve convergence of properties with increasing basis set size (i.e. decrease the errors associated with the use of basis sets of finite size). Modern computational packages use only nuclear-position-dependent basis sets. In the same way, derivatives with respect to magnetic fields can use basis functions which either (a) are not or (b) are functions of magnetic field. The standard choice for the latter are so-called London orbitals or gauge-invariant atomic orbitals (GIAOs). The use of GIAOs vastly reduces basis set error and is increasingly *de rigueur*

in computation of magnetic properties (e.g. NMR shielding tensors). With regard to the implementation of AATs in CADPAC, DALTON and GAUSSIAN, we should add that DALTON and GAUSSIAN use GIAOs, while CADPAC does not.

With respect to basis set size we can simply note that (a) accuracy increases with increasing basis set size; (b) the rate of increase in accuracy is rapid at small sizes and less rapid at large sizes; (c) with respect to the ratio of accuracy to size, such basis sets as 6-31G* are generally regarded as optimal for calculations on organic molecules.

Finally, in DFT calculations there is the question of the density functional. The accuracy of DFT calculations varies greatly with the choice of functional. The exact functional gives exact results. Very crude functionals give very inaccurate results. Functionals used in the recent past can be grouped into three classes: (a) local; (b) non-local/gradient-corrected; (c) hybrid. Overall, the relative accuracy is local

$$\text{local} < \text{non-local} < \text{hybrid}.$$

At this time, hybrid functionals are generally regarded as state-of-the-art. There are many: the original is 'B3PW91'; a popular choice is 'B3LYP'. Undoubtedly, current functionals will be soon replaced by yet more accurate functionals.

Implementation

In **Figure 1** we compare predicted absorption and VCD spectra for camphor to experiment. Predictions are based on DFT calculations using the B3PW91 functional and the 6-31G* basis set. AATs are calculated using GIAOs. The calculations were carried out using the GAUSSIAN program. Spectra are simulated from frequencies, dipole strengths and rotational strengths assuming Lorentzian bandshapes of constant width (half width at half height 4 cm^{-1}).

Focussing first on the absorption spectrum, we observe an excellent one-to-one correspondence between predicted and experimental spectra. That is: we can assign the bands of the experimental spectrum to fundamental excitations in such a way that the pattern of frequencies and intensities is extremely similar to that predicted. One notices an overall shift of the predicted spectrum to higher frequency. This shift is attributable both to error in the calculated harmonic frequencies and to anharmonicity, which uniformly lowers experimental frequencies with respect to harmonic frequencies. Calculations on very small molecules, where harmonic frequencies are known, indicate that the two contributions are of the same sign and comparable in magnitude. It is also to be noted that almost all bands of the experimental spectrum can be assigned to fundamental transitions.

Figure 2 Comparison of calculated and experimental rotational strengths for (1*R*, 4*R*)-(+)-camphor. *R* values are in 10^{-44} esu² cm². The straight line has a slope +1.

Conversely, the number of overtone and combination bands observable is very small. It is clear that the HA is a very good approximation and that the neglect of anharmonicity in predicting spectra is not a serious deficiency.

We turn now to the VCD spectrum. Each VCD band corresponds to an absorption band. The assignment of the experimental absorption spectrum can thus be transferred directly to the experimental VCD spectrum. Comparison of predicted and experimental VCD intensities, fundamental by fundamental, can then be carried out. As seen in **Figure 1**, the agreement is qualitatively excellent. Quantitative comparison of calculated and experimental rotational strengths, the latter obtained by Lorentzian analysis of the experimental VCD spectrum, is shown in **Figure 2**.

Discussion

At the present time, calculation of absorption and VCD spectra within the harmonic approximation using DFT is computationally straightforward at the 6-31G* basis set level using GAUSSIAN 98 and standard parallel computers for organic molecules containing ≤ 200 atoms. For smaller molecules, larger basis sets can be used, yielding results of higher accuracy. For molecules with >200 atoms one awaits further developments in computational algorithms and machine speed. The accuracy of DFT/6-31G* calculations using hybrid density functionals, illustrated in **Figure 1**, is already impressive. Further improvements in functionals, to be expected in the near future, will bring predicted spectra into even closer agreement with experiment.

There are two major deficiencies in the theoretical treatment of VCD described above: the neglect of anharmonicity and of solvent effects. Anharmonicity is relatively unimportant in the mid-IR spectral region, but becomes much more important at higher frequencies, e.g. in the C–H stretching region. Its inclusion for large molecules constitutes one of the remaining major theoretical challenges for the theory of VCD. Solvent effects are relatively unimportant in simple non-polar solvents such as CCl₄. However, they become much more important in solvents interacting much more strongly with solute molecules. Inclusion of solvent effects in such solvents, especially water, constitutes another major challenge for the theory of VCD.

We are here restricted to the theory of VCD. Its applications, past and future, are beyond the scope of our discussion. It is worth emphasizing, nevertheless, that the development of an accurate, computationally efficient methodology for the prediction of VCD spectra is of enormous consequence for the practical application of VCD spectroscopy to problems of stereochemistry in chiral molecules. In particular, the determination of absolute configuration in organic molecules containing ≤ 200 atoms is now practicable using VCD spectroscopy.

Introduction

Chiral organic molecules are currently of widespread interest to organic chemists and pharmaceutical chemists. Chiral drugs, for example, omeprazole, are of increasing importance in the pharmaceutical industry. Since the two enantiomers of a chiral drug generally possess different pharmaceutical activities, the resolution and clinical testing of both enantiomers is a prerequisite to the development of the optimum drug. The increasing importance of chiral drugs has stimulated the development of improved techniques, especially chromatographic, for the resolution of racemic mixtures of chiral molecules, and of new asymmetric synthesis methods. In addition to synthetic chiral molecules, naturally occurring molecules ('natural products'), which are invariably chiral and generally enantiomerically enriched, are of increasing interest as drugs, or leads for new drugs. Many natural products have been used in folk medicine for centuries, and such molecules are now receiving increasing attention.

As a consequence of the increasing attention to chiral organic molecules, methods for the structural characterization of chiral molecules are of increasing importance. The absolute configuration (AC) and conformations of a chiral molecule are important factors in determining its pharmaceutical activity. Although X-ray crystallography and NMR spectroscopy are powerful techniques for

structural determination, their application to the determination of ACs and to conformational analysis is limited. The Bijvoet method for determining ACs using X-ray crystallography requires the presence of a 'heavy' atom. NMR spectra are not enantiomerically sensitive and cannot be used to determine ACs. As a consequence, chiroptical spectroscopy is widely used by organic chemists in determining ACs and for conformational analysis.

The famous chirality-sensitive optical properties of chiral molecules are optical rotation (OR) and circular dichroism (CD). OR originates in the difference in the refractive indices of left- and right-circularly polarized light (n_L and n_R). CD is the differential absorption of left- and right-circularly polarized light: $\Delta A = A_L - A_R$. First measured by Cotton in 1895, CD is often referred to as the Cotton effect (CE). Both the OR and the CD of a chiral molecule are frequency-dependent; measurement of OR and CD over a range of frequencies gives optical rotatory dispersion (ORD) and CD spectra. The ORD and CD spectra of the two enantiomers of a chiral molecule are of equal magnitude and opposite sign: that is, mirror-image enantiomers give mirror-image ORD and CD spectra. Consequently, the AC of a chiral molecule can, in principle, be determined from its ORD or CD spectrum.

The use of ORD and CD for the characterization of the stereochemistries of chiral organic molecules expanded rapidly after World War II as a result of the development of improved instrumentation for the measurement of ORD and CD spectra and of 'sector rules' correlating the signs of ORD and CD spectra with ACs. The most famous sector rule was the 'octant rule,' which predicts the sign of the ORD and CD of the $n \rightarrow \pi$ electronic excitations of carbonyl groups.

Historically, the applications of ORD and CD spectroscopies have been predominantly in the visible-ultraviolet spectral region. ORD and CD in this region originate in electronic excitations. In the 1970s, the question arose: Can ORD and CD, originating in vibrational excitations, be measured in the infrared (IR) spectral region? The measurement of IR ORD was first attempted, but was unsuccessful. At the University of Southern California (USC) in the late 1960s, the authors had built a CD instrument operating in the visible–near-IR spectral region (down to $\sim 3300\text{ cm}^{-1}$), whose principal purpose was the measurement of electronic magnetic circular dichroism (MCD) spectra. In 1973,

extension of the frequency limit of this instrument to lower frequencies led to the authors' first measurements of VCD spectra. Key to this breakthrough was the construction of a new photoelastic modulator (PEM) with a ZnSe optical element, transmitting down to $\sim 650 \text{ cm}^{-1}$. Since then, VCD instrumentation has developed in both frequency range and sensitivity. Currently, Fourier transform (FT) VCD instruments are commercially available.

After it was shown that VCD spectra could be measured, the utilization of VCD spectroscopy by organic chemists for the stereochemical characterization of chiral molecules required the development of a methodology permitting the relationship between the structure of a molecule and its VCD spectrum to be predicted. The intensity of the CD of the vibrational transition $i \rightarrow f$ is determined by its rotational strength:

$$R(i \rightarrow f) = \text{Im} \left[\left\langle i \left| \vec{\mu}_{\text{el}} \right| f \right\rangle \cdot \left\langle f \left| \vec{\mu}_{\text{mag}} \right| i \right\rangle \right] \quad [1]$$

where $\vec{\mu}_{\text{el}}$ and $\vec{\mu}_{\text{mag}}$ are the electric dipole and magnetic dipole operators, respectively. The electric dipole transition moment, $\langle i | \vec{\mu}_{\text{el}} | f \rangle$, simultaneously determines the dipole strength of the transition:

$$D(i \rightarrow f) = \left| \left\langle i \left| \vec{\mu}_{\text{el}} \right| f \right\rangle \right|^2 \quad [2]$$

which determines the unpolarized absorption intensity of the transition (i.e., its intensity in the standard IR spectrum). Within the Born–Oppenheimer (BO) approximation for the electronic and vibrational wavefunctions and the harmonic approximation for the vibrational motion, $\langle i | \vec{\mu}_{\text{el}} | f \rangle$ for the fundamental transition of the i th normal mode is given by

$$\langle 0 | (\mu_{\text{el}})_{\beta} | 1 \rangle_i = \left(\frac{\hbar}{4\pi v_i} \right)^{1/2} \sum_{\lambda\alpha} S_{\lambda\alpha,i} P_{\alpha\beta}^{\lambda} \quad [3]$$

where v_i is the harmonic frequency of the i th mode, the $S_{\lambda\alpha,i}$ matrix defines the relationship between its normal coordinate Q_i and the Cartesian displacement coordinates, $X_{\lambda\alpha}$ (λ = nucleus; α = x , y , z):

$$X_{\lambda\alpha} = \sum_i S_{\lambda\alpha,i} Q_i \quad [4]$$

and $P_{\alpha\beta}^{\lambda}$ is the atomic polar tensor (APT) given by

$$P_{\alpha\beta}^{\lambda} = \left(\frac{\partial (\mu_{\text{el}}^G)_{\beta}}{\partial X_{\lambda\alpha}} \right)_0 \quad [5]$$

where $\vec{\mu}_{\text{el}}^G$ is the electric dipole moment of the ground electronic state, G , and $\left(\partial (\mu_{\text{el}}^G)_{\beta} / \partial X_{\lambda\alpha} \right)_0$ is its derivative with respect to $X_{\lambda\alpha}$ at the equilibrium geometry $\vec{R}_0$. $P_{\alpha\beta}^{\lambda}$

is the sum of electronic and nuclear contributions, $E_{\alpha\beta}^{\lambda}$ and $N_{\alpha\beta}^{\lambda}$:

$$\begin{aligned} P_{\alpha\beta}^{\lambda} &= E_{\alpha\beta}^{\lambda} + N_{\alpha\beta}^{\lambda} \\ E_{\alpha\beta}^{\lambda} &= 2 \left\langle \left(\frac{\partial \psi_G}{\partial X_{\lambda\alpha}} \right)_0 \left| (\mu_{\text{el}}^e)_{\beta} \right| \psi_G^0 \right\rangle \\ N_{\alpha\beta}^{\lambda} &= (Z_{\lambda} e) \delta_{\alpha\beta} \end{aligned} \quad [6]$$

where $(\partial \psi_G / \partial X_{\lambda\alpha})_0$ is the derivative of the ground state electronic wavefunction with respect to $X_{\lambda\alpha}$ at $\vec{R}_0$ and $\vec{\mu}_{\text{el}}^e$ is the electronic contribution to the electric dipole moment operator. Prediction of vibrational dipole strengths and IR spectra thus requires the calculation of the frequencies and normal coordinates of the $3N - 6$ (N = number of nuclei) normal modes and of the APTs.

To predict vibrational rotational strengths and VCD spectra, the magnetic dipole transition moments must also be calculated. At the time of the earliest VCD measurements, no quantum-mechanical equation for magnetic dipole vibrational transition moments existed, and quantum-mechanically rigorous calculations of vibrational rotational strengths were impossible. Fortunately for the development of VCD spectroscopy, such an equation was soon developed by Stephens. The Stephens equation for the magnetic dipole transition moment of the fundamental transition of the i th normal mode within the harmonic approximation is:

$$\langle 0 | (\mu_{\text{mag}})_{\beta} | 1 \rangle_i = (4\pi\hbar^3 v_i)^{1/2} \sum_{\lambda\alpha} S_{\lambda\alpha,i} M_{\alpha\beta}^{\lambda} \quad [7]$$

where $M_{\alpha\beta}^{\lambda}$ are atomic tensors, termed atomic axial tensors (AATs) by Stephens, and are given by

$$\begin{aligned} M_{\alpha\beta}^{\lambda} &= I_{\alpha\beta}^{\lambda} + J_{\alpha\beta}^{\lambda} \\ I_{\alpha\beta}^{\lambda} &= \left\langle \left(\frac{\partial \psi_G}{\partial X_{\lambda\alpha}} \right)_0 \left| \left(\frac{\partial \psi_G}{\partial H_{\beta}} \right)_0 \right. \right\rangle \\ J_{\alpha\beta}^{\lambda} &= \frac{i}{4\hbar c} \sum_{\gamma} (Z_{\lambda} e) R_{\lambda\gamma}^0 \varepsilon_{\alpha\beta\gamma} \end{aligned} \quad [8]$$

where $I_{\alpha\beta}^{\lambda}$ and $J_{\alpha\beta}^{\lambda}$ are the electronic and nuclear contributions to $M_{\alpha\beta}^{\lambda}$, and $(\partial \psi_G / \partial H_{\beta})_0$ is the derivative of the ground state electronic wavefunction of the molecule in the presence of the external magnetic field perturbation $\sum_{\beta} -(\mu_{\text{mag}}^e)_{\beta} H_{\beta}$ with respect to H_{β} , where $\vec{\mu}_{\text{mag}}^e$ is the electronic magnetic dipole moment operator. Compared to the calculation of APTs, the calculation of AATs requires simply the additional calculation of the magnetic field derivatives $(\partial \psi_G / \partial H_{\beta})_0$. Combining eqns [1], [3], and [7] then gives the Stephens equation for the vibrational rotational strength of the fundamental transition, $0 \rightarrow 1$, of the i th normal mode:

$$R(0 \rightarrow 1)_i = \hbar^2 \sum_{\beta} \sum_{\lambda\alpha, \lambda'\alpha'} \left(S_{\lambda\alpha,i} P_{\alpha\beta}^{\lambda} \right) \left(S_{\lambda'\alpha',i} M_{\alpha'\beta}^{\lambda'} \right) \quad [9]$$

At the time of the development of the Stephens equation for vibrational rotational strengths, the most accurate predictions of IR spectra were being made using *ab initio* methods for the prediction of vibrational force fields, frequencies, and normal coordinates and of APTs. It was therefore clear that the most accurate predictions of VCD spectra would require *ab initio* vibrational force fields, frequencies, and normal coordinates and APTs and AATs. From the beginning therefore, the implementation of the Stephens equation has been carried out using *ab initio* methods. The first implementations used the Hartree–Fock (HF)/self-consistent field (SCF) methodology, within the *ab initio* programs GAUSSIAN and CADPAC. Over the next decade it became clear that considerable improvement in the accuracy of VCD spectra, calculated using *ab initio* methods, would result from the use of methods more accurate than the HF/SCF method. In 1996, this expectation led to the application of density

functional theory (DFT) to the calculation of AATs, using GIAOs (to give origin-independent rotational strengths) by Drs. J. R. Cheeseman and M. J. Frisch at Gaussian, Inc., within the GAUSSIAN program. Together with the calculation of vibrational force fields and APTs using DFT, and thence vibrational dipole strengths and IR spectra, which had been available since 1992, this development permitted the prediction of vibrational rotational strengths and VCD spectra using DFT. Comparison of DFT and HF/SCF VCD spectra for molecules whose experimental VCD spectra were available showed clearly that the DFT VCD spectra were much more accurate, as long as state-of-the-art density functionals were used for the DFT calculations. As a result, the DFT method has become the basis for all calculations of VCD spectra, using the Stephens equation for vibrational rotational strengths.

To reliably determine the AC of a chiral molecule by comparison of its experimental VCD spectrum to the

Figure 1 The experimental IR and VCD spectra of (+)-**1** in CCl₄ solution (0.0765 M). The VCD spectrum is normalized to 100% ee.

Figure 2 Comparison of the B3PW91/TZ2P and experimental IR spectra of **1**. The bandshapes of the calculated spectra are Lorentzian ($\gamma = 4.0 \text{ cm}^{-1}$). The numbers define the fundamental modes of **1** contributing to the spectral bands.

VCD spectra of the two enantiomers, calculated using the Stephens equation and DFT, a basis set giving minimal basis set error and a density functional as close to the exact functional in accuracy as possible are required. The relative accuracies of different basis sets and functionals in predicting VCD spectra have been evaluated using a number of conformationally rigid molecules, including methyl-oxirane, camphor, fenchone, and α -pinene. It has been shown that the basis sets TZ2P and cc-pVTZ are close to the complete basis set limit, whereas much smaller basis sets such as 6-31G* are substantially less accurate. In addition, it has been shown that Becke-hybrid density functionals, such as B3PW91 and B3LYP, give much more accurate VCD spectra than local and gradient-corrected pure functionals, such as LSDA and BLYP. Consequently, optimum choices of basis set and functional are TZ2P/cc-pVTZ and B3PW91/B3LYP. These basis sets and functionals have been used in the determinations of the ACs of chiral organic molecules discussed in the following section.

Organic molecules are frequently conformationally flexible: that is, at room temperature, the temperature at

which experimental VCD spectra are measured, multiple conformations are present in equilibrium. In the case of a conformationally flexible molecule, prediction of the VCD spectrum requires conformational analysis to be carried out: that is, the prediction of the geometries, relative free energies, and equilibrium populations of the populated conformations. The VCD spectra of the populated conformations are then calculated and weighted by the conformational populations and summed to predict the 'conformationally averaged VCD spectrum.' The reliability of this spectrum is dependent on the accuracy of the conformational analysis; if the number of populated conformations is incorrectly predicted and if the relative free energies and equilibrium populations are inaccurately predicted, the predicted VCD spectrum is less accurate than that of a conformationally rigid molecule. At the present time, the optimum conformational analysis procedures for large flexible organic molecules are the following: (1) a molecular mechanics force field (MMFF) is used to identify the stable conformations of the molecule with energies within at least 20 kcal mol^{-1} of the global minimum conformation;

Figure 3 Comparison of the B3PW91/TZ2P spectra of (S)-1 and (R)-1 to the experimental VCD spectrum of (+)-1. The bandshapes of the calculated spectra are Lorentzian ($\gamma = 4.0 \text{ cm}^{-1}$). The numbers define the fundamental modes of 1 contributing to the spectral bands.

(2) the MMFF conformations are then optimized using DFT (with the same basis sets and functionals to be used for VCD calculations), and their harmonic frequencies calculated to prove that the conformations are stable and to permit the calculation of their free energies. This protocol has been utilized in the determinations of the ACs of conformationally flexible chiral organic molecules discussed in the following sections.

How to Determine the Absolute Configuration of a Chiral Organic Molecule Using VCD Spectroscopy

First, the experimental VCD spectrum of a solution of an enantiomer of the molecule of known OR is measured in the mid-IR spectral region, together with the corresponding IR spectrum, using a solution of sufficiently

dilute concentration that Beer's Law is obeyed, guaranteeing the absence of contributions to the IR and VCD spectra from molecular aggregates. Second, conformational analysis of the molecule is carried out to determine the number, structures, relative free energies, and populations of the conformations in equilibrium at room temperature (the temperature at which the experimental IR and VCD spectra are measured). Third, the harmonic vibrational frequencies, dipole strengths, and rotational strengths of the fundamental transitions of all significantly populated conformations are predicted using DFT, and the IR and VCD spectra obtained thence, using Lorentzian bandshapes (since the bandshapes of vibrational transitions of molecules in liquid solutions are Lorentzian). The IR and VCD spectra of each conformation are then weighted by its predicted equilibrium population and the population-weighted spectra of all conformations summed, giving the 'conformationally averaged' IR and VCD spectra. Fourth, the predicted IR spectrum is used to assign the experimental IR spectrum, automatically leading to the assignment of the experimental VCD spectrum (since the IR and VCD of each fundamental transition occur at identical frequencies). Fifth, the predicted VCD spectra of the two enantiomers are compared to the experimental VCD spectrum. The VCD spectrum of the enantiomer with the same AC as the experimental enantiomer should be in excellent agreement with the experimental VCD spectrum, and the VCD spectrum of the enantiomer with opposite AC should exhibit zero agreement. The comparison of the calculated and experimental VCD spectra thus defines the AC of the experimental enantiomer. Sixth, to define the quantitative agreement of the calculated and experimental VCD spectra, the calculated and experimental rotational strengths of the transitions whose VCD is observed are compared. The experimental rotational strengths are obtained by Lorentzian fitting of the experimental VCD spectrum (in solutions obeying Beer's Law vibrational bandshapes are Lorentzian). The reliability of the AC deduced from the VCD spectrum is quantitatively established by comparison of the quantitative agreement of the calculated rotational strengths of the two enantiomers with the experimental rotational strengths.

To illustrate this procedure, the determination of the ACs of the chiral alkane anti-*trans*-anti-*trans*-anti-*trans*-perhydrotriphenylene, **1**, and the chiral thiazinoxadiazol-3-one, **2**, is discussed.

Perhydrotriphenylene, **1**

The perhydroderivative of triphenylene, (**Scheme 1**), has D_3 symmetry and is therefore chiral.

Optically active **1** was first synthesized by Farina and Audisio and its AC assigned as $R(-)/S(+)$ by calculation of its $[\alpha]_D$, and by conversion to a keto-derivative

Scheme 1

Figure 4 Comparison of calculated rotational strengths for (*R*)-**1** and (*S*)-**1** to the experimental rotational strengths of (+)-**1**. Rotational strengths R are in 10^{-44} esu² cm². The straight lines of slope +1 are the 'lines of perfect agreement.'

whose AC was determined using its Cotton effect and the octant rule. Very recently, gas chromatography was applied by Schürch et al. to the resolution of PHTP. The AC of PHTP has been determined using VCD spectroscopy, using a sample of (+)-1 with ee 93.5%, obtained by gas chromatography by Professors Schürch and Hulliger. The mid-IR and VCD spectra of a CCl₄ solution of (+)-1 are shown in **Figure 1**.

Conformational analysis of **1** using the MMFF94 force field finds four conformations **a–d**; in the lowest energy conformation, **a**, all cyclohexane rings have a chair conformation; in each of the higher energy conformations, one of the peripheral cyclohexane rings has a twisted-boat conformation. B3LYP/6-31G* DFT reoptimization of the MMFF94 conformations **a–d**, followed by harmonic frequency calculations, leads to the relative energies and free energies of the four conformations and, thence, using Boltzmann statistics, to their room-temperature equilibrium populations. Conformation **a** is predicted to be > 99% of the equilibrium mixture; thus, **1** is predicted to be effectively a conformationally rigid molecule.

DFT calculations of the IR and VCD spectra of conformation **a** of **1** have been carried out using the B3LYP and B3PW91 functionals and the 6-31G* and TZ2P basis sets. Comparison of the predicted IR spectra to the experimental IR spectrum showed that the best agreement with experiment was produced by the combination of B3PW91 and TZ2P. The B3PW91/TZ2P IR spectrum is compared to the experimental IR spectrum in **Figure 2** and leads to unequivocal assignment of the experimental spectrum, as detailed in **Figure 2**. (Note that the calculated frequencies are higher by a few

percent than the experimental frequencies, due to the neglect of anharmonicity in the calculations.) This, in turn, leads to the assignment of all of the bands in the VCD spectrum with frequencies identical to bands in the IR spectrum. Comparison of the B3PW91/TZ2P VCD spectra of the two enantiomers of conformation **a** of **1** to the experimental VCD spectrum of (+)-**1**, shown in **Figure 3**, leads unambiguously to the conclusion that *S* is the AC of (+)-**1**. The detailed assignment of the experimental VCD spectrum, based on the B3PW91/TZ2P assignment of the IR spectrum and the B3PW91/TZ2P VCD spectrum, is shown in **Figure 3**. The rotational

Scheme 2

Figure 5 Comparison of the B3PW91/6-31G* rotational strengths of (*S*)-**1** and the experimental rotational strengths of (+)-**1**. Rotational strengths *R* are in 10^{−44} esu² cm².

Figure 6 (a) IR spectrum of (±)-**2**. (b) VCD spectrum of (+)-**2**. The gap at ~900 cm^{−1} is due to strong absorption of the CCl₄ solvent.

strengths of the observed VCD bands are then determined by Lorentzian fitting of the experimental VCD spectrum. Comparison to the sums of the B3PW91/TZ2P rotational strengths of (*R*)-**1** and (*S*)-**1** (see **Scheme 1**) for the fundamental transitions assigned to the experimental VCD bands is shown in **Figure 4**. The agreement of the (*S*)-**1** rotational strengths with the experimental rotational strengths of (+)-**1** is nearly perfect, whereas the agreement of the (*R*)-**1** rotational strengths is as bad as it can be. This comparison thus definitively establishes that the AC of (+)-**1** is *S*. In addition, it supports the prediction that only conformation **a** is significantly populated, and proves that the B3PW91 functional is a very accurate functional and that the TZ2P basis set is an excellent approximation to the complete basis set. The importance of the use of a basis set leading to rotational strengths with little basis set error is emphasized by comparison of the rotational strengths of (*S*)-**1** predicted by B3PW91 with the 6-31G* basis set to the experimental rotational strengths of (+)-**1**, shown in **Figure 5**.

The AC of (+)-**1**, determined using VCD, is the same as that assigned by Farina and Audisio. At this time, there is no longer any uncertainty in the AC of **1**.

8-(4-Br-phenyl), 8-ethoxy, 5-methyl, 8 H-[1,4]thiazino-[3,4-c][1,2,4] oxadiazol-3-one, **2**

A range of thiazino-oxadiazolones were recently synthesized by Budriesi et al. and their activities as calcium entry channel blockers assayed. The most active compound synthesized was **2** (see **Scheme 2**); its activity was

Scheme 3

Figure 7 Comparison of the conformationally averaged B3PW91/TZ2P IR spectrum of **2** to the experimental IR spectrum of (±)-**2**. The numbers are those of the fundamentals. When no conformation is specified the fundamentals of **a**, **b**, and **c** are unresolved.

To better understand the mechanism of the calcium entry channel blocker activity of **2**, its AC has been determined using VCD, using samples of (+)-**2** and (–)-**2** resolved by Professor Gasparrini using HPLC. The

2 is a very conformationally flexible molecule: the six-membered thiazino ring is expected to be nonplanar and have more than one conformation; the phenyl group can rotate around the C8–C13 bond; the ethoxy group can rotate around the C8–O10 and O10–C11 bonds. As expected, conformational analysis using the MMFF94 force field finds a large number of conformations. B3LYP/6-31G* DFT reoptimization of these conformations leads to 13 stable conformations with relative energies and free energies within 8 kcal mol⁻¹. Luckily, only the three lowest energy conformations, **a–c** **Scheme 3**, are predicted to have room-temperature equilibrium populations >2%.

Figure 8 Comparison of the conformationally averaged B3PW91/TZ2P VCD spectra of (*S*)-**2** and (*R*)-**2** to the experimental VCD spectrum of (+)-**2**. The numbers are those of the fundamentals. When no conformation is specified the fundamentals of **a**, **b**, and **c** are unresolved.

In each of these three conformations the thiazino ring has the same conformation, but the conformation of the 8-ethoxy group is different.

DFT calculations of the IR and VCD spectra of conformations **a–c** of **2** have been carried out using B3LYP and B3PW91 functionals and the 6-31G* and TZ2P basis sets. Comparison of the conformationally averaged IR spectrum of **2** to the experimental IR spectrum showed that the best agreement with experiment was provided by the combination of B3PW91 and TZ2P. The B3PW91/TZ2P IR spectrum is compared to the experimental IR spectrum in **Figure 7** and leads to the assignment of the experimental spectrum detailed in **Figure 7**. It is important to note that in the calculated spectrum, for some fundamentals, the bands of the conformations **a–c** are sufficiently different in frequency that they are resolved. In these cases, the conformational splittings are also observed in the experimental spectrum, providing support for the conformational analysis of **2**. The assignment of the experimental IR spectrum leads to assignment of the bands in the VCD spectrum with frequencies identical to bands in the IR spectrum. Comparison of the B3PW91/TZ2P conformationally averaged VCD spectrum of the two enantiomers of **2** to the experimental VCD spectrum of (+)-**2**, shown in **Figure 8**, leads unambiguously to the conclusion that the AC of (+)-**2** is *S*. The detailed assignment of the experimental VCD spectrum, based on the B3PW91/TZ2P assignment of the IR spectrum and the B3PW91/TZ2P VCD spectrum, is shown in **Figure 8**. Again, as with the IR spectrum, resolution of the contributions of different conformations to the VCD spectra of several modes is clearly observed, further supporting the conformational analysis of **2**. The rotational strengths of the observed VCD bands are then determined by Lorentzian fitting of the experimental VCD spectrum. The B3PW91/TZ2P rotational strengths of each observed VCD band are then calculated by summing the population-weighted rotational strengths of the fundamentals assigned to the band. Comparison of these calculated rotational strengths for the two enantiomers of **2** to the experimental rotational strengths of (+)-**2** is shown in **Figure 9**. The agreement of the (*S*)-**2** rotational strengths with the experimental rotational strengths of (+)-**2** is excellent (except for modes 52–54), whereas the agreement of the (*R*)-**2** rotational strengths is terribly bad. This comparison thus definitively establishes that the AC of (+)-**2** is *S*. In addition, it further confirms the excellent accuracies of the B3PW91 functional and the TZ2P basis set in predicting vibrational rotational strengths.

The AC of **2**, determined using VCD, shows that the enantiomer of **2**, (–)-**2**, having the higher calcium entry channel blocker activity has the AC *R*. If **2** eventually becomes a commercial pharmaceutical, it will probably be the *R*-(–) enantiomer that is used.

Figure 9 Comparison of calculated rotational strengths for (*R*)-**2** and (*S*)-**2** to the experimental rotational strengths of (+)-**2**. Rotational strengths *R* are in 10^{-44} esu² cm².

Applications of VCD Spectroscopy to the Determination of ACs of Chiral Organic Molecules, Using the Stephens Equation for Vibrational Rotational Strengths and DFT

Since the application of DFT to the calculation of vibrational rotational strengths in the GAUSSIAN program, in addition to molecules **1** and **2**, the VCD spectra of many chiral organic molecules have been analyzed using DFT. Molecules whose studies have been published are shown in **Figure 10**. In some cases, for example, the monoterpenes,

Figure 10 Molecules whose VCD have been studied using DFT.

Figure 11 Comparison of experimental and conformationally averaged B3PW91/TZ2P IR and VCD spectra of **32** for the range 800–1800 cm^{-1} . Fundamentals are numbered. Red and green numbers indicate bands of conformations **a/a'** and **b/b'**, respectively. Black numbers indicate superpositions of bands of conformations **a**, **a'**, **b**, and **b'**. Bandshapes of the calculated spectra are Lorentzian ($\gamma = 4.0 \text{ cm}^{-1}$).

camphor **7**, fenchone **8**, and α -pinene **9**, the ACs had previously been unambiguously determined, and the studies focused primarily on the relative accuracies of DFT calculations using different combinations of functionals and basis sets. In some other cases, for example, Tröger's base, **13**, and the chromenone, **25**, although their ACs had been previously assigned, the reliability of these ACs was

questionable. The authors' VCD studies of these molecules focused primarily on establishing their ACs definitively. In the case of Tröger's base, **13**, its AC had been assigned to be $R,R(+)$ by Mason et al., using its ECD spectrum together with the Coupled Oscillator theory of electronic rotational strengths. The VCD study of Tröger's base showed that its AC is in fact $R,R(-)/S,S(+)$, the opposite

Figure 12 Comparison of experimental and B3PW91/TZ2P rotational strengths of **32**. Calculated rotational strengths are for (2*R*,7*S*,20*S*,21*S*)- and (2*S*,7*R*,20*R*,21*R*)-**32**. Experimental rotational strengths are for (+)-**32**. Calculated rotational strengths are population-weighted averages. Rotational strengths *R* are in $10^{-44} \text{ esu}^2 \text{ cm}^2$.

of that assigned by Mason et al. In the case of **25**, its AC had been assigned to be *R*(−)/*S*(+) by Besse et al., using the Bijvoet X-ray crystallography method. The VCD study of the acetate derivative of **25** showed that the AC of **25** is in fact *R*(+)/*S*(−) the opposite of that assigned by Besse et al. Studies of **13** and **25** demonstrated the greater power of VCD spectroscopy in determining ACs compared to the coupled oscillator ECD method and the Bijvoet X-ray crystallography method when applied to molecules not having a ‘heavy atom.’

Several of the VCD studies have been motivated by the need to understand the mechanisms of asymmetric synthesis reactions. For example, the mechanism of the asymmetric synthesis of chiral sulfoxides by reaction of

the corresponding sulfides with tert-butyl-hydroperoxide, together with $\text{Ti}(\text{iso-PrO})_4$ and optically active 1,2-diphenylethane-1,2-diol, was investigated in collaboration with Professor Rosini by determination of the ACs of 1-Me-2-Me-naphthyl-sulfoxide, **17**, 1-thiochroman-sulfoxide, **18**, and 1-thiochromanone-sulfoxide, **19**. The mechanism of the asymmetric synthesis of chiral phenyl-glycidic-acid derivatives via asymmetric epoxidation of *trans*-cinnamic acid derivatives using oxone and a keto-bile acid was investigated in collaboration with Professor Bortolini by determination of the ACs of the *o*-Br, *m*-F, and *p*-CH₃ derivatives of phenyl glycidic acid, **26**. The mechanism of the Baeyer–Villiger oxidation of a chiral bicyclo[3.3.1]nonane-2,7-dione, giving the chiral keto-lactone, **11**, was investigated in collaboration with Professor Butkus by determination of the AC of **11**. The mechanism of the asymmetric synthesis of spir-pentylcarboxylic acid via deamination of spir-pentylamine was investigated in collaboration with Professor Wiberg by determination of the ACs of the methyl ester of spir-pentylcarboxylic acid, **21**, and spir-pentyl acetate, **22**.

Another focus of the authors’ studies has been the determination of the ACs of natural products. Since the early studies of the natural products camphor, fenchone, and α -pinene, it has been clear that this could become a major application of VCD spectroscopy. In 1998, the authors studied the natural product frontalinal, **10**, an insect pheromone. Recently, the authors have returned to this area, studying the cytotoxic sesquiterpene quadron, **12**; the alkaloids schizozygine, **28**, and isoschizogaline and isoschizogamine, **29**; and the iridoids plumericin and isoplumericin, **30**, and prismatomerin **31**. The studies of the alkaloids and iridoids have demonstrated the power of DFT-based VCD spectroscopy in determining the ACs of very large natural product molecules. It is expected that this area of application of VCD will grow rapidly in the near future and, as a result, significantly impact the elucidation of the stereochemistries of natural products, especially those of potential pharmaceutical interest. For this reason, the following section discusses the studies of the alkaloids and iridoids **28–31**.

Applications of VCD Spectroscopy to the Determination of the ACs of Natural Products

The Alkaloids Schizozygine, Isoschizogaline, and Isoschizogamine

The alkaloids schizozygine, isoschizogaline, and isoschizogamine were isolated from the East African plant, *Schizozygia caffaeoides*, extracts of which have been used in traditional medicine in Kenya for the treatment of skin

Figure 13 Comparison of the experimental and B3PW91/TZ2P IR and VCD spectra of **33** for the range 800–1800 cm^{-1} . The numbers define the fundamentals contributing to resolved bands. Red and green numbers refer to fundamentals of **1a** and **1b**, respectively. Black numbers are used when the bands of **1a** and **1b** are not resolved. Bands shapes of the calculated spectra are Lorentzian ($\gamma = 4.0 \text{ cm}^{-1}$).

diseases. The spectroscopic properties and chemical reactions of schizozigine (**32**) led Renner et al. to the conclusion that the structure is:

The structures of isoschizogaline (**33**) and isoschizogamine (**34**) have been recently shown by NMR to be:

Figure 14 Comparison of the experimental and B3PW91/TZ2P IR and VCD spectra of **34** for the range 800–1850 cm^{-1} . The numbers define the fundamentals contributing to resolved bands. Red, green, and blue numbers refer to fundamentals of **Ia**, **Ib**, and **Ic**, respectively. Black numbers are used when the bands of **Ia**, **Ib**, and **Ic** are not resolved. Bandshapes of the calculated spectra are Lorentzian ($\gamma = 4.0 \text{ cm}^{-1}$).

The relative configurations of **32**–**34** result from their NMR studies. Until very recently, however, no determination of the ACs of these natural products had been reported. In 2006, in collaboration with Professors Urbanová and Hájíček, the authors determined the ACs of these three alkaloids, using VCD.

Schizozygine

Naturally occurring **32** exhibits a positive $[\alpha]_{\text{D}}$ value. The IR and VCD spectra of (+)-**32** were measured using CDCl_3 solutions. Conformational analysis of **32** identified four conformations with B3LYP/6-31G*

energies within a range of $0.4 \text{ kcal mol}^{-1}$. The relative free energies, room-temperature equilibrium populations, IR spectra, and VCD spectra of these four conformations were predicted using the functionals B3LYP and B3PW91 and the basis set TZ2P. Comparison of the conformationally averaged IR spectra to the experimental spectrum led to the conclusion that the B3PW91/TZ2P spectrum gave the best agreement with experiment. The B3PW91/TZ2P IR spectrum is compared to the experimental spectrum in **Figure 11**, leading to the assignment of the experimental IR spectrum, also shown in **Figure 11**. The assignment of the experimental IR spectrum simultaneously leads to the assignment of the

Figure 15 Comparison of experimental and B3PW91/TZ2P rotational strengths of **33**. Experimental rotational strengths are for (–)-**33**. Calculated rotational strengths are for (2*R*,7*R*,20*S*,21*S*)- and (2*S*,7*S*,20*R*,21*R*)-**33**. Calculated rotational strengths are population-weighted averages of conformations **1a**, **1b**, and **11a**. Rotational strengths *R* are in 10^{-44} esu² cm².

experimental VCD spectrum, as also shown in **Figure 11**. Comparison of the B3PW91/TZ2P VCD spectrum of (2*R*,7*S*,20*S*,21*S*)-**32** to the experimental VCD spectrum of (+)-**32** shows that the agreement is excellent, and that the AC of **32** is therefore (2*R*,7*S*,20*S*,21*S*)-(+). Quantitative comparison of the calculated rotational strengths for both enantiomers of **32** and the experimental rotational strengths, obtained by Lorentzian fitting, is shown in **Figure 12**. Unquestionably, the calculated rotational strengths for (2*R*,7*S*,20*S*,21*S*)-**32** are in far superior agreement with the experimental rotational strengths for (+)-**32** than are the calculated rotational strengths for (2*S*,7*R*,20*R*,21*R*)-**32**. The AC of (+)-**32** is unambiguously shown to be 2*R*,7*S*,20*S*,21*S*.

Figure 16 Comparison of experimental and B3PW91/TZ2P rotational strengths of **34**. Experimental rotational strengths are for (–)-**34**. Calculated rotational strengths are for (2*R*,7*R*,20*S*,21*S*)- and (2*S*,7*S*,20*R*,21*R*)-**34**. Calculated rotational strengths are population-weighted averages of conformations **1a–1e** and **11a**. Rotational strengths *R* are in 10^{-44} esu² cm².

Isoschizogaline and Isoschizogamine

Naturally occurring **33** and **34** both exhibit negative $[\alpha]_D$ values. The IR and VCD spectra of (–)-**33** and (–)-**34** were measured in CDCl₃ solutions. Analysis of the IR and VCD spectra followed the same protocol as used for **32**. Again, the B3PW91/TZ2P conformationally averaged IR spectra of **33** and **34** were in the best agreement with the experimental spectra. These spectra and the resulting assignments of the experimental IR and VCD spectra are shown in **Figures 13** and **14**. The B3PW91/TZ2P VCD spectra of (2*R*,7*R*,20*S*,21*S*)-**33** and (2*R*,7*R*,20*S*,21*S*)-**34**, also shown in **Figures 13** and **14**, are in excellent agreement with the experimental VCD spectra of (–)-**33** and (–)-**34**, leading to the conclusion that the ACs of both are (2*R*,7*R*,20*S*,21*S*)-(–). Quantitative

Figure 17 Comparison of the experimental and B3PW91/TZ2P IR and VCD spectra of **35** for the range 750–1900 cm^{-1} . The numbers define the fundamentals contributing to resolved bands. Red, green, and cyan numbers refer to fundamentals of **a**, **b**, and **c/d**, respectively. Black numbers are used when the bands of **a** and **b** are not resolved. Bandshapes of the calculated spectra are Lorentzian ($\gamma = 4.0 \text{ cm}^{-1}$).

comparisons of calculated rotational strengths for both enantiomers of **33** and **34** to the experimental rotational strengths of (–)-**33** and (–)-**34**, shown in **Figures 15** and **16**, definitively confirm that the ACs of both (–)-**33** and (–)-**34** are 2*R*,7*R*,20*S*,21*S*.

activity. Later, Albers-Schönberg and Schmid isolated **35** and its isomer, isoplumericin, **36**, from *Plumeria rubra* var. *alba* and, on the basis of chemical and spectroscopic studies, assigned their structures and ACs as:

The Iridoids Plumericin, Isoplumericin, and Prismatomerin

The iridoid natural product plumericin, **35**, was first isolated from the plant *Plumeria multiflora* by Little and Johnstone and shown to exhibit anti-fungal and anti-bacterial

(1*R*,5*S*,8*S*,9*S*,10*S*)-**35**

(1*R*,5*S*,8*S*,9*S*,10*S*)-**36**

Figure 18 Comparison of the experimental and B3PW91/TZ2P IR and VCD spectra of **36** for the range 750–1900 cm^{-1} . The numbers define the fundamentals contributing to resolved bands. Red, green, and cyan numbers refer to fundamentals of **a**, **b**, and **c/d**, respectively. Black numbers are used when the bands of **a** and **b** are not resolved. Bandshapes of the calculated spectra are Lorentzian ($\gamma = 4.0 \text{ cm}^{-1}$).

Total syntheses of racemic **35** and **36** and X-ray crystal structure determinations of the natural products (+)-**35** and (+)-**36** have confirmed these structures but have not confirmed or disproved the ACs. Very recently, Elsässer et al. concluded, from comparison of the ECD spectra of (+)-**35** and (+)-**36** to ECD spectra calculated using semi-empirical MO theory, that the ACs assigned by Albers-Schönberg and Schmid were incorrect. In 2006, in collaboration with Professors Krohn and Kurtán, the authors redetermined the ACs of these two iridoids, using VCD, with the results discussed in the following text.

Very recently, a new, highly cytotoxic iridoid has been isolated from *Prismatomeris tetrandra*, and named prismatomerin. Chemical and spectroscopic studies

identified the structure of prismatomerin, **37**, as:

differing from **35** and **36** simply by the substitution of a methyl group by a *para*-phenol group. The specific rotation, $[\alpha]_D$, of **37** is -136 , similar in magnitude but

Figure 19 Comparison of B3PW91/TZ2P calculated and experimental rotational strengths of **35**. Experimental rotational strengths are for (+)-**35**. Calculated rotational strengths are for (1*R*,5*S*,8*S*,9*S*,10*S*)- and (1*S*,5*R*,8*R*,9*R*,10*R*)-**35**. Calculated rotational strengths are population-weighted averages. Rotational strengths *R* are in 10^{-44} esu² cm².

opposite in sign to the $[\alpha]_D$ of **35**, +204, raising the possibility that the AC of **37** might be opposite to that of **35**. To evaluate this conclusion, the AC of **37** was determined using the VCD of its acetate derivative, **38**

(to minimize intermolecular hydrogen bonding), with the result discussed in the following text.

Figure 20 Comparison of B3PW91/TZ2P calculated and experimental rotational strengths of **36**. Experimental rotational strengths are for (+)-**36**. Calculated rotational strengths are for (1*R*,5*S*,8*S*,9*S*,10*S*)- and (1*S*,5*R*,8*R*,9*R*,10*R*)-**36**. Calculated rotational strengths are population-weighted averages. Rotational strengths *R* are in 10^{-44} esu² cm².

Plumericin and isoplumericin

Naturally occurring **35** and **36** exhibit positive $[\alpha]_D$ values. The IR and VCD spectra of (+)-**35** and (+)-**36** were measured using CDCl₃ solutions. Conformational analysis of **35** and **36** identified four conformations with B3LYP/6-31G* energies within a range of 2.0 kcal mol⁻¹. Analysis of the experimental IR and VCD spectra of (+)-**35** and (+)-**36** followed the same protocol as discussed earlier in the case of **32**. Again, the B3PW91/TZ2P conformationally averaged IR and VCD spectra of (1*R*,5*S*,8*S*,9*S*,10*S*)-**35** and (1*R*,5*S*,8*S*,9*S*,10*S*)-**36** were in the best agreement with the experimental spectra. These spectra and the resulting assignments of the experimental spectra are shown in **Figures 17** and **18**. The B3PW91/TZ2P VCD spectra of

Figure 21 Comparison of experimental and B3PW91/TZ2P IR and VCD spectra of **38** for the range 790–1900 cm^{-1} . The calculated spectra are conformationally averaged and simulated using Lorentzian bandshapes ($\gamma = 4.0 \text{ cm}^{-1}$). The red, green, and blue numbers indicate bands from conformations **Aa–d**, **Ba–d**, and **Ca–d**, respectively; the black numbers indicate bands from conformations **Aa–d** and **Ba–d**.

(1*R*,5*S*,8*S*,9*S*,10*S*)-**35** and (1*R*,5*S*,8*S*,9*S*,10*S*)-**36** are in excellent agreement with the experimental VCD spectra (+)-**35** and (+)-**36**, showing that the ACs of both are (1*R*,5*S*,8*S*,9*S*,10*S*)-(+) . Quantitative comparisons of calculated rotational strengths for both enantiomers of **35** and **36** to the experimental rotational strengths of (+)-**35** and (+)-**36**, shown in **Figures 19** and **20**, definitively confirm that the ACs of both (+)-**35** and (+)-**36** are 1*R*,5*S*,8*S*,9*S*,10*S*.

Prismatomerin

Naturally occurring **37** exhibits a negative $[\alpha]_{\text{D}}$ value. The $[\alpha]_{\text{D}}$ of the acetate derivative of **37**, **38**, is also negative. The IR and VCD spectra of (–)-**38** were measured using a CDCl_3 solution. The B3PW91/TZ2P

conformationally averaged IR and VCD spectra of (1*R*,5*S*,8*S*,9*S*,10*S*)-**38** are compared to the experimental IR and VCD spectra in **Figure 21**, leading to the assignments of the experimental IR and VCD spectra also shown in **Figure 21**. Comparison of calculated and experimental rotational strengths, the former for both enantiomers of **38**, is shown in **Figure 22**. The good agreement of the calculated VCD spectrum of (1*R*,5*S*,8*S*,9*S*,10*S*)-**38** and the experimental VCD spectrum of (–)-**38**, together with the superior agreement of the calculated rotational strengths for (1*R*,5*S*,8*S*,9*S*,10*S*)-**38**, compared to those for (1*S*,5*R*,8*R*,9*R*,10*R*)-**38**, with the experimental rotational strengths lead to the conclusion that the AC of (–)-**38** is 1*R*,5*S*,8*S*,9*S*,10*S*. It follows that the AC of (–)-**37** is also 1*R*,5*S*,8*S*,9*S*,10*S*.

Figure 22 Comparison of B3PW91/TZ2P calculated and experimental rotational strengths of **38**. Experimental rotational strengths are for (–)-**38**. Calculated rotational strengths are for (1*R*,5*S*,8*S*,9*S*,10*S*)- and (1*S*,5*R*,8*R*,9*R*,10*R*)-**38**. Calculated rotational strengths are population-weighted averages. Rotational strengths *R* are in 10^{-44} esu² cm². The numbers indicate the fundamentals of the points.

The ACs of **37** and **35** are thus identical. The conclusion that they are opposite, derived from the signs of their $[\alpha]_D$ values, is thus wrong.

Conclusion

It has been demonstrated that the prediction of the VCD spectra of the enantiomers of a chiral molecule using the Stephens equation for vibrational rotational strengths and the DFT methodology, together with optimally chosen basis sets and density functionals, is of sufficient reliability to permit the unambiguous determination of the

ACs of organic molecules. In the cases of conformationally rigid molecules, for example, perhydrophenylene, **1**, predicted rotational strengths are in excellent quantitative agreement with experimental rotational strengths. The minor differences can be attributed to both experimental errors and theoretical errors. The accuracies of experimental VCD spectra depend on the magnitudes of artifact signals generated by the spectrometer utilized, due to imperfections in optics. The accuracies of the predicted VCD spectra depend on the accuracies of the basis set and density functional used (as discussed earlier) and, also, on the magnitudes of contributions to the vibrational rotational strengths due to vibrational anharmonicity and solvent effects, which are not included in the predicted spectra. Except when Fermi resonance is significant, as is always the case for the C–H stretching modes of organic molecules, anharmonicity clearly causes very small contributions to the rotational strengths of vibrational transitions in the mid-IR ($\lesssim 2000$ cm⁻¹), the region universally used in determining ACs. As long as the solvent chosen for the measurement of the experimental VCD spectrum interacts weakly with the solute molecule, solvent effects clearly cause very small contributions to vibrational rotational strengths. The most commonly used solvents are CCl₄, CHCl₃, CDCl₃, and CS₂, because they absorb minimally in the mid-IR spectral region and interact minimally with the majority of organic molecules.

In the cases of conformationally flexible molecules, for example, the thiazino-oxadiazolone **2** and the alkaloids and iridoids **32–37**, there is an additional source of error in the predicted VCD spectra: errors in the predicted conformational relative free energies and equilibrium populations. For some conformationally flexible molecules, calculated and experimental rotational strengths agree less well than is the case for conformationally rigid molecules, most likely due to errors in predicted conformational populations. Examples of molecules where this is observed are the alkaloid and iridoid molecules **32–37** (see Figures 11–22).

The prediction of vibrational rotational strengths and VCD spectra will therefore be improved in accuracy in the future by the following developments: (1) the development of more accurate density functionals; (2) the inclusion of anharmonicity; (3) the inclusion of solvent effects; and (4) improvement in the prediction of the equilibrium populations of conformationally flexible molecules. Such advances will increase the reliability of the ACs of organic molecules determined using VCD spectroscopy.

The analysis of VCD spectra is substantially easier and more reliable than the analysis of electronic CD (ECD) spectra, for two reasons. First, vibrational transitions have much smaller bandwidths than electronic transitions and, as a result, VCD spectra are much more

highly resolved than ECD spectra. Second, vibrational rotational strengths only depend on the wavefunction of the ground electronic state, whereas electronic rotational strengths depend on the wavefunctions of both ground and excited electronic states. The calculation of the ground electronic state wavefunction is more accurate than the calculation of excited electronic state wavefunctions and so vibrational rotational strengths are more accurately predicted than electronic rotational strengths. The comparison of calculated and experimental electronic rotational strengths is therefore more difficult and less accurate than the comparison of calculated and experimental vibrational rotational strengths. Consequently, ACs are more easily and reliably determined using VCD, compared to ECD.

What are the limitations of VCD in determining ACs? If the molecule is enormously large, DFT calculations are impractical. At this time, therefore, bio-organic molecules such as proteins and nucleic acids cannot be analyzed. If the molecule is enormously flexible, and the number of populated conformations is enormously large, the prediction of its VCD spectrum becomes very time-consuming and less reliable. For these reasons, VCD is not universally applicable to the determination of ACs. Nevertheless, for the majority of medium-sized organic molecules VCD is a practical technique. Undoubtedly, many more applications will be carried out in the future.

After a slow start in the nineteenth century, infrared (IR) spectroscopy saw a rapid increase in use and for a while, from 1945 onwards, was the most widespread method for determining the chemical structures of molecules. In the 1960s it became increasingly supplemented and overshadowed by other techniques, but developments in instrumentation have vastly improved its sensitivity and speed and enabled it to be applied to previously intractable problems. While research applications are many, there is overwhelming analytical and industrial usage.

The development of Raman spectroscopy has generally lagged behind that of IR owing to greater technical difficulties. The advent of the laser was the most important event in its history and has enabled many special and esoteric Raman experiments to be conceived. It is no longer confined mainly to the laboratory and is now used extensively in industry.

Beginnings: IR and Raman Spectroscopy before the Second World War

The astronomer William Herschel, better known as the discoverer of the planet Uranus, first detected IR radiation in 1800. Using a glass prism to refract the rays of the sun, he observed a rise in temperature in a thermometer positioned beyond the red limit of the visible spectrum (**Figure 1**).

Over the next one hundred years the essential nature of IR radiation was slowly established, electrical methods of measurement were developed and a number of materials such as rock salt were found to be largely transparent to it and thus useful as refracting elements. Interest was mainly directed to the physics of the subject, with little attention given to any possibilities for application to chemistry.

Near the end of the nineteenth century, however, a number of workers observed that many specific classes of organic compounds absorbed in characteristic regions of the IR spectrum. A monumental compilation of such bands, mostly from his own measurements, was published by W.W. Coblentz in 1905. One of his spectra is shown in **Figure 2** (plotted in terms of % transmittance) and can be compared with a modern-day version of the same compound in **Figure 3** (plotted in terms of absorbance). At the time, the precise mechanism for absorption was

unclear, but it was soon realized that it was derived from what could be considered to be intramolecular vibrations. By the 1930s, a fairly complete theory encompassing the relation of dipole moment change to band intensity, selection rules, molecular symmetry and anharmonicity was available for both vibrational and rotational motions.

In 1928, C.V. Raman announced the discovery of the effect that now bears his name. In fact he had already observed it a few years before as a weak 'residual fluorescence' from highly purified organic liquids. It is generally considered, however, that the effect had been predicted by A. Smekal. Raman was awarded the Nobel Prize, the second Indian to be so honoured. Although the Raman effect was found to be very weak, the relation of selection rules to symmetry differed, so that results could complement those from IR absorbance.

Instrumentation

Detection of IR radiation could be done by using bolometers or thermocouples, but point-by-point plotting of galvanometer readings made measurement of spectra somewhat tedious. IR-sensitive photographic film was available later and was occasionally used. Technical obstacles were many, however; for example, the DC output from detectors could not be amplified and most galvanometers had long response times. Material for dispersion of IR radiation was scarce, rock salt of the quality and size suitable for prisms being difficult to obtain. Machines were single-beam and baselines were a major problem owing to the normal variations in laboratory heat background. Most instruments were built in-house, though commercial models were available, the first being introduced by Adam Hilger Ltd of the UK in 1913. It is illustrated in **Figure 4**.

The KBr disk method was not to be invented until 1952, so solids were usually sampled by mulling or reflection from whole crystals. The majority of samples studied were either liquids or gases.

By contrast, Raman spectra were usually easier to acquire so long as the sample was not coloured or turbid. Working in the visible region allowed simple spectrographs with silica/glass optics to be used and suitable photographic films were readily available, though long exposures were generally required. Discharge lamps,

Sheppard, FRS, and reproduced with permission from Hilger Analytical.

usually mercury vapour, provided a rather weak source of excitation radiation with a broad, diffuse background.

Studies between the Wars

The benefits of theory soon allowed vibrational spectroscopy to move away from simple characterization to deductions about the shape and symmetry of simple

molecules. The observation that gaseous CO₂ yielded three fundamental modes of vibration, of which two were seen in the IR only and the other in the Raman only, immediately determined that it must be linear and symmetric. The tetrahedral structure of methane was confirmed by the lack of any observable pure rotational Raman spectrum. Such results gave valuable support to the developing theories of chemical bonding.

Knowledge of the actual frequency values enabled the calculation of the vibrational partition functions. Thermodynamic quantities of interest such as the heat capacity in the gas phase at different temperatures could then be estimated with great precision. In addition, the force constants of very simple molecules could be determined.

IR spectroscopy gave a dramatic illustration of the existence of hydrogen bonding, a suspected new type of molecular attraction. For instance, at high temperatures in the gas phase, formic acid yielded the expected single fundamental from O–H stretching at about 3570 cm^{-1} . But at lower temperatures and in the liquid, this band disappeared to be replaced by a new one at near 3080 cm^{-1} .

While most attention was naturally given to the IR region below 4000 cm^{-1} , some measurements were made in the near IR (NIR), i.e. above 4000 cm^{-1} , often for no other reason than ease of experimentation. Overtones and combination bands were of course of interest in their own right but could also sometimes be used to make deductions about lower-frequency fundamental modes.

First Flowering: IR Spectroscopy to the 1970s

Developments in electronics during the 1930s made measurements of IR spectra somewhat easier. Successful application to a number of tasks connected with the Second World War, such as monitoring the composition of Axis petroleum samples to determine origin, led to a considerable expansion in activities.

Considerable effort was put into organic group frequency correlations, and compilations soon became available for general use. These were utilized extensively for detailed structural characterization of organic compounds. The boon to organic chemists can be appreciated by considering the methods that had been available to them before. Elemental analysis could only give overall composition and ultraviolet–visible (UV-visible) spectroscopy little more than some idea of the degree or type of unsaturation. A limited number of chemical group types were detectable by chemical spot tests.

Moreover, IR spectroscopy was also applied to other work such as quantitative analysis and the study of physical interactions between molecules. The general rise of scientific activities in both universities and industry naturally led to a rise in demand for IR facilities and the 1940s saw the first commercial automatically recording spectrometers. Spectra were now produced routinely as continuous plots. Single-beam instruments were rapidly superseded by double-beam ones and gratings came into general use.

Dispersive Double-Beam Spectrometers

In double-beam instruments compensation was, with one or two exceptions, by the optical null method whereby a servomotor drove a comb into the reference beam to minimize the signal difference between it and the sample beam as it was attenuated to varying degrees by absorbance. Movement of the comb was mechanically geared to a pen, which thus recorded the spectrum as a trace on a moving chart.

Sample and reference beams were alternately presented to the detector by means of mirrors and a chopper rotating at a frequency of several hertz, thus allowing selective amplification of the signal difference, which was fed to the servomotor. Thermal detectors continued to be used for many years but with developments, such as the pneumatic Golay cell, for greater sensitivity.

Good-quality large alkali halide crystals could now be grown on an industrial scale, so that fabrication of prisms and other optical components did not present any difficulties. In particular, use of synthetic KBr allowed spectra to be measured down to 400 cm^{-1} ; pre-war natural NaCl (rock salt) prism spectrometers had a lower limit of about 650 cm^{-1} owing to the higher frequency absorption edge of the salt.

Rotation of the prism or grating was controlled by a cam to allow the spectral trace to be recorded in either constant wavelength or wavenumber. This cam was coupled to the slits to vary their width in order to keep the radiation reaching the detector roughly constant. Resolution therefore varied over the spectrum. Positional accuracy and repeatability were poor owing to backlash and wear in the mechanical linkages; most specifications quoted values around $\pm 0.5\text{ cm}^{-1}$.

The inherent disadvantage of the optical null mechanism was the attenuation of the reference beam, so that accuracy and response time became worse as sample transmittance (%*T*) decreased. Linearity of response depended on how well the comb had been machined. Theoretically it was impossible for the equipment to measure 0% *T*. Scanning had to be slow to avoid excessive pen lag. Reliable quantitative analysis was difficult though possible.

The amounts of sample required for good spectra of a solid was generally of the order of a milligram. By utilizing beam condensers and the best instruments, adequate spectra could be obtained from small samples of the order of a hundred nanograms.

Commercial Instruments

Several companies built spectrometers; based in the USA were Perkin-Elmer, Beckman, Baird and Cary; in the UK, Grubb-Parsons, Hilger (**Figure 5**) and Unicam (later Pye-Unicam). Instruments were also built in France, Germany (both West and East), Japan and the USSR. The

Figure 5 An early automatically recording IR spectrometer, the Hilger model D209 introduced in 1940. The spot from a mirror galvanometer was focused onto photographic film fixed to a rotating drum. Later during the Second World War, this machine was developed into the first commercial double-beam (ratio recording) IR spectrometer. Photograph courtesy of Professor N. Sheppard, FRS, and reproduced by permission of Hilger Analytical.

commonest optical layout used was the Littrow arrangement which had the virtue of compactness. Low-cost instruments were introduced in the 1950s, some only with prisms though all were soon sold with gratings instead. Their relative cheapness and ease of use were major factors in the rapid expansion in the practice of IR spectroscopy. Research-grade models usually had a grating monochromator with a fore-prism. Two or more gratings with auto changeover were required to cover the whole range.

During the latter part of the period, prisms disappeared and more advanced features were built into dispersive spectrometers such as computer interfaces, principally for data acquisition only. Ratio recording became standard in place of the optical null. However, the Perkin-Elmer model 983, introduced in 1982, demonstrated the benefits that computerization could bring to instrument control. Grating rotation was carried out directly by a stepper motor under the command of a microprocessor. With no mechanical cam, position repeatability ($\pm 0.005\text{ cm}^{-1}$) was, in consequence, almost as good as that of FT-IR instruments.

Applications

A pre-eminent use already described was structure determination of organic compounds. The KBr disk technique allowed complete and unmarred spectra of solids to 400 cm^{-1} . Extensive collections of spectra (both literature and commercial) of organics, inorganics, pharmaceuticals and industrial chemicals now appeared.

A result of great topical interest in the late 1940s was the recognition that penicillin contained a fused four-membered lactam ring on the basis of several bands,

including one at an unusually high value, near 1780 cm^{-1} , from the amidic carbonyl stretching mode.

Because of the distinctive fingerprint nature of the spectra of individual substances, a very common application was, and continues to be, compound verification in forensic identification and quality assurance to meet pharmacopoeial and other standards set by regulatory authorities.

The sensitivity of IR bands to changes in physical state led to numerous studies concerned with the thermodynamics of hydrogen bonding in solvents and the influence of solvent effects (donor/acceptor capacities). Phase transitions (polymorphism) in solids could easily be detected by changes in band intensity and position.

Inorganic and metal-organic compounds also received attention in structural studies. For instance, IR spectroscopy of metal carbonyl complexes could easily distinguish between terminal and bridging ligands.

Access to computing (mainframe) facilities from the 1950s onwards provided the means to analyse the fundamental mode frequencies of a polyatomic molecular structure on the basis of harmonic oscillation and obtain force constants. These could be transferred to other structures and the procedure reversed so as to estimate frequencies for cases where a spectrum was difficult to interpret. While fraught with difficulties, mainly because there were usually many more force constants to estimate than frequencies, such work did at least highlight the fact that many vibrational modes are strongly coupled to each other and that few bands can normally be assigned to specific bond motions.

Data handling was never more than very primitive. Although the largest commercial collections of spectra offered searching facilities, for example by matching of

most prominent bands, these were not very successful in practice even for pure compounds.

The rapid spread of mass spectrometry (MS) and nuclear magnetic resonance (NMR) spectroscopy from the 1960s caused IR spectroscopy to be sidelined in many areas of analysis. NMR was much better at elucidating many fine details of molecular structure, while detection limits were lower using MS.

Renaissance: The (Fourier) Transformation of IR Spectroscopy

IR interferometers seem first to have been tried out for examining the very low signal levels of IR emission from astronomical sources. They were shortly also employed for far-IR spectroscopy where low source output made measurement extremely difficult using conventional spectrometers below 200 cm^{-1} .

There was sufficient interest for several far-IR instruments to be made available commercially from the late 1950s, but one drawback was the difficulty of numerically converting the interferograms to recognizable spectra. With only mainframe computers available, instrument-based digital computing was not feasible. RIIC/Beckman marketed a machine that stored data, after analogue-to-digital conversion, on magnetic core memory. The data were then reconverted back to analogue to be fed into an electronic wave analyser to generate the spectrum.

Ironically, these interferometers could not be used to advantage in the mid-IR region ($4000\text{--}400\text{ cm}^{-1}$) in most circumstances. This was because, with scan speeds in minutes, signal levels were so large that the noise was well below the threshold of even the smallest bit of the best (16-bit) ADCs obtainable. However, by the early 1960s, Block Engineering of the USA had developed a fast scanning interferometer. Providentially, lasers (for accurate path difference referencing), minicomputers and the Cooley–Tukey fast Fourier transform (FFT) algorithm soon all appeared. A Block subsidiary, Digilab, exploited these devices to produce the first commercial mid-IR Fourier transform (FT-IR) spectrometer, the model FTS-14, in 1969.

They were followed during the 1970s by other companies, most of whom had had no previous experience in the IR field but made computers and data loggers, such as Nicolet and Bruker. The machines offered were principally research grade, though Digilab made an early and substantial entry into the specialist market for quality control of semiconductors.

Most manufacturers of dispersive instruments opted not to enter the new arena, presumably because of the costs involved in investment in the new technology, and in consequence left the business altogether as demand for

dispersive instruments dried up. A major exception was Perkin-Elmer who, although starting late, had the resources to participate in a big way. Although offering research-grade instruments as well, they particularly targeted the analytical market, in which they were soon to be a major supplier.

At least twenty manufacturers worldwide have offered FT-IR spectrometers in recent years, several of them for niche markets such as dedicated gas analysis and space science.

Advantages of Interferometry in the Mid IR

Two factors were judged to be of major importance: the Fellgett (multiplex) and Jacquinot (throughput) advantages. The Jacquinot advantage, though large, and foremost at higher wavenumbers, was found, however, to be largely cancelled out by the much decreased performance (at the high modulation frequencies imposed by fast scanning interferometers) of the early pyroelectric detectors used, both factors having a roughly similar wavenumber dependency. Traditional thermal effect detectors such as thermocouples were far too slow.

As other factors (e.g. beam splitter versus grating efficiency) were of lesser importance, this meant that overall advantage in signal to noise (S/N) ratio of mid-IR FT instruments over dispersive was basically determined by multiplexing only. Strict comparisons were not possible, though, because FT instruments ran at constant resolution unlike dispersive where resolution varied somewhat across the spectrum.

Thus for spectra run at moderate resolution and over limited spectral range, FT machines with pyroelectric detectors were not strikingly better than dispersive. This was because the multiplex advantage (for FTIR) is no better than $1/2\sqrt{M}$, where M is the number of resolution elements.

However, for low signal levels a quantum detection, MCT (mercury cadmium telluride) was soon developed that had much greater sensitivity at high modulation rates and thus did not trade off the Jacquinot advantage. This allowed FT spectrometers to tackle situations that dispersive could not even attempt and to go some way in competing with and complementing MS in trace analysis. Various advances in component design (e.g. sources) saw a considerable improvement in general performance during the 1970s.

The Connes advantage claimed for interferometers was that laser referencing would yield much greater wavelength accuracy and reproducibility. The latter was crucial for both signal averaging and spectral subtraction but, as the Perkin-Elmer company had shown, this could almost be matched by dispersive.

Photometric accuracy and reproducibility were actually worse than with the best ratio-recording grating

instruments, owing mainly to sample reflection and emission back into the interferometer.

Fashion probably played a significant role in the cessation of dispersive spectrometer manufacture as the high S/N provided by FT machines was not required when sample was abundant and sample preparation took much longer than measurement.

Applications

Interferometers made far-IR spectroscopy possible, and enabled observation of lattice vibrations of crystals, low-frequency skeletal motions of organics and the stretching modes of heavy atoms. In the mid-IR region interest was not so much in new vibrations as in old ones in new and difficult situations, now accessible because of the high S/N available. Multitudes of hitherto indifferent samples suffering from low transmission were now directly amenable without resort to complex pre-preparation. Because data were obtained and stored in digital form, spectra could readily be manipulated and spectral subtraction to remove solvent bands from solution spectra, assess purity and reveal impurities became a popular activity.

High S/N, and in addition fast scanning, enabled events as rapid as fractions of seconds to be monitored. Thus FT-IR spectroscopy was applied with considerable success as a detection method for gas chromatography (GC) and manufacturers were obliged to offer suitable devices. However, optimizing the interface took a surprisingly long time; waiting on GC column technology was partly to blame. Some 20 years elapsed from the early 1970s before minimum identifiable limits, starting in micrograms, reached the mid-picogram level with the advent of cryogenic trapping methodology.

While many biological/biochemical samples had been studied by dispersive instruments, the difficulties of dealing with aqueous solutions was a severe limitation. Now, however, this general field became a major area of research attention for application of FT-IR in the 1980s. Of interest was the sensitivity of vibrational modes to subtle changes in molecular environment of the type crucial to biological mechanism and structure studies. Particular topics were how cell membrane conformations were affected by interactions with other chemicals or general physicochemical effects, and analyses of protein secondary structure.

Instrumentation

The GC-IR interface was the first of many specialized accessories that began to appear in increasing numbers during the 1980s. They included interfaces to various forms of chromatography (the combination being known as a hyphenated method), photoacoustic and diffuse

reflectance cells and microscopes. Spectrometer design was influenced so as to avoid the inconvenience of changeover. Interferometers were therefore built with multiple beam ports to allow two or more accessories to be permanently connected. With such developments and the continuing miniaturization of computing hardware, the large floor-standing FT spectrometers of the 1970s were superseded by the modular benchtop machines of the 1980s.

One of the more recent significant developments of the interferometer has been the step scanning modification. This has allowed, among other things, the monitoring of fast processes on the timescale of single data point acquisition so that, for example, vibrational spectra of some excited states can be obtained.

Finally, the interferometer was not to be all-conquering, however, as simple filter spectrometers were found to be useful for many dedicated monitoring purposes. Tuneable IR lasers have also been applied to gas monitoring, but their general usefulness has been limited by the range of wavelengths that can be output.

The Coming of the Black Box

The necessary provision of computers in FT-IR soon led to much more than simple data manipulation. After much unfulfilled promise and wasted effort, data transfer systems became fairly standardized and reliable by the late 1980s. With the universal adoption of the JCAMP format, spectra in digital form became truly portable and could become part of the business of laboratory information management systems (LIMS). More interestingly, they could be directly matched into large digital spectral databases for automatic identification or structural analysis by expert systems.

In parallel, the 1980s also saw considerable development in the application of software for data analysis and instrument control. By this time, software was accounting for more than half the development cost of an FT-IR system.

Acronyms Galore: The Impact of the Laser on Raman Spectroscopy

Unlike the case for IR spectroscopy, there was little development in the immediate post-war years, so that for a long time practice was mainly confined to a few academic institutions.

An improved source, the mercury arc, a helical discharge lamp surrounding a cylindrical sample tube, yielded much-increased light energy, though probably equal in importance was the advent of photoelectric recording. The latter facility enabled the production of scanning instruments. Two companies, Cary and Hilger & Watts, offered models, the former fielding an

image slicing device that attempted to overcome the optical incompatibility of the extended area of the mercury arc source and the narrow spectrometer slits.

Apart from the weakness of the spectra, the range of materials that could be examined was restricted by problems thrown up by the sample itself. Coloured samples absorbed source and scattered signal and possessed the propensity to fluoresce, which could easily drown out the Raman signal.

The advantages offered by the laser to Raman spectroscopy were recognized almost as soon as it had been demonstrated in 1960. It was to revolutionize the technique by providing dramatic increases in sensitivity (Figure 6) and the opportunity for unusual experiments by virtue of nonlinear effects that it could induce in many materials.

The continuous gas lasers were found to be most useful. The principal advantage of the laser in general over the mercury arc lay in the small point-source area that allowed larger flux throughput for a given spectrometer étendue.

Where formerly grams of material were needed, now milligram quantities, as solid powders, liquid or solutions in capillary tubes, were routinely amenable to examination.

The beckoning opportunities soon led several manufacturers (e.g. Spex, Jarrel-Ash, Coderg and Perkin-Elmer) to bring out new equipment, while older designs (Cary) were modified to accommodate the new type of source. Instruments were of course expensive compared to dispersive IR spectrometers as the optical requirements were far more stringent. Two coupled monochromators were necessary to cut down stray light from the exciting line. The Czerny-Turner layout was most common, the monochromators usually, but not always, being arranged for additive dispersion. Figure 7 shows a very early photographic/mercury arc Raman spectrum of CCl_4 for comparison with what could be achieved with an automatically recording spectrometer of the late 1960s (Figure 8).

Photoelectric detection for Raman spectroscopy initially suffered from poor sensitivity in the red, but this

was rectified during the 1980s when many cheap photomultiplier tubes became available. Rather more expensive were multichannel detectors, originally used for fast time-resolved experiments in the 1970s. Their take-up was slow but by the late 1980s very sensitive charge-coupled devices (CCDs) developed for astronomy were being incorporated in spectrographs for relatively mundane analytical work.

Complementing Infrared

Compared to IR spectroscopy, the Raman technique was found to possess some advantages, one particular being the comparative ease in dealing with aqueous solutions. In the biochemical sphere this meant, for example, that ionization behaviour and pH change could be studied; even before the arrival of the laser, amino acids had been demonstrated to exist as zwitterions.

For a long time a major disadvantage was the common occurrence of interference from fluorescence, especially often encountered in biological material. A redeeming feature of Raman spectroscopy, however, was the many special experiments that could be performed.

Nonlinear Effects and Other Esoterica

The high power densities available from lasers were found to be capable of inducing a number of strange (nonlinear) Raman effects, though many were of limited applicability to problems in chemistry. Typical examples included SIRS (stimulated inverse Raman scattering), RIKES (Raman-induced Kerr effect spectroscopy) and the hyper Raman effect.

Probably the most useful was found to be CARS (coherent anti-Stokes Raman scattering), in which the signal could be detected largely free of background such as fluorescence. It was particularly beneficial in examining combustion processes in flames. Hopes that it might provide the complete answer to the fluorescence problem were to be largely unfulfilled owing mainly to its technical complexity.

Other interesting and useful discoveries did not require high-power excitation. Resonance Raman scattering (RRS) arises in certain samples when the laser excitation wavelength falls within an electronic absorbance band. RRS bands can be several orders of magnitude stronger than normal. One application was to employ small-molecule ligands exhibiting RRS as probes in the active sites of enzymes, thus avoiding major interference from the complex spectrum of the protein.

In 1974 news came that the Raman spectrum of pyridine was considerably enhanced when absorbed on a roughened silver substrate. This effect was named SERS (surface-enhanced Raman scattering) and has since been observed from many other compounds and other metals. Electrochemistry was an early application. Inevitably, experimenters were to combine the effect with RRS to create SERRS, which in some circumstances can equal fluorescence for sensitivity of detection.

Instrumental Developments

FT-Raman spectroscopy was introduced in 1986 and it is now available as a bolt-on to many FT-IR machines. Interestingly, interferometers might have been used

earlier for Raman spectroscopy if the laser had not been invented, as their large circular aperture could have coped advantageously with the extended source area of the mercury arc. As it was, the multiplexing capability was needed to boost sensitivity so as to satisfactorily observe the weak spectra produced by a near-IR laser. The rationale was that fluorescence was largely eliminated. Thus, high-quality spectra of dyes, for instance, could be obtained that had formerly been impossible. Unfortunately, as overtones and combinations of H₂O vibrations possess significant absorbance in the near IR, spectra from aqueous solutions were affected.

An earlier development was the reintroduction of the spectrograph made possible by the availability of multi-channel detectors. CCDs, with sensitivity equal to the traditional photomultiplier and up to 1024 channels, thus provided a considerable multiplexing advantage. They allowed the construction of small, rugged instruments able to acquire good-quality spectra very rapidly. Coupled to fiberoptic sampling devices, such spectrographs have recently found considerable use for process monitoring in industry.

A very useful accessory has been the microscope. Here there is a significant advantage over IR spectroscopy as spatial resolution is higher owing to the shorter wavelength of the source radiation.

Out of the Orphanage: The Rise of Near-IR Spectroscopy

The NIR region was for long neglected, a curiosity for users of many research-grade UV-visible and mid-IR spectrometers that had been provided with extended range capabilities. This was not unexpected, as absorption bands in the region originate from either uncommon electronic transitions in inorganic compounds or broad and heavily overlapped overtones and combinations of vibrational fundamentals. The latter are mostly derived from X–H stretching modes in organic compounds. In consequence, spectra, particularly of mixtures, are not easy to interpret.

Experimentally, however, the spectra are easy to observe, thick samples being tractable in either transmission or reflection without preparation. As the spectra seldom possess many narrow features that could be unduly affected by instrumental or other factors, robust methods for quantitation were possible. With the arrival of cheap instrumental computing from the 1980s onwards and the development of multivariate analysis methodology, NIR spectroscopy has undergone considerable expansion in use. It is now widely applied to automated, rapid and precise quantitative analyses in agriculture, industrial process control and noninvasive medical examinations. A

typical and early example was determination of the protein content of grain and flour.

Most work is now done with dispersive and simple filter analysers. Though S/N is not usually a problem, FT-NIR and filter/CCD machines are more popular.

Full Circle: IR and Raman Spectroscopy into the New Millennium

Originally IR spectra were measured point by point; they then became continuous and now are again digital in nature. Spectrometers were single-beam, then double-beam, and now are almost all single-beam once more. With the introduction of spectrographs coupled to multichannel detectors, Raman spectroscopy is also in a sense back where it used to be, when photographic film effectively provided a multiplicity of channels. NIR CCDs are presently available that cover some of the range and the future possibilities of usable array detection right down into the mid IR could eventually spell a general return to dispersive techniques. Further into the future, fully tuneable IR lasers would remove even the need for a dispersing element for IR spectroscopy. If the rationale for interferometers, hitherto their advantage in throughput, is lost, then their disadvantages such as poor photometric accuracy and mechanical complexity could mean retention only in special circumstances.

Hand in hand with increasing sophistication of spectrometers and software, much of which runs transparently to the user, has gone an overall de-skilling of operatives. This is inevitable (and usually desirable) given the workload and demands on modern analytical laboratories and industrial processes. There are obvious dangers, however, as the theory behind the methodology is beyond many scientific workers, as are the ramifications of many spectrometer function operations on the input data. The days are long gone when spectroscopists built and maintained their own machines, synthesized the chemicals they studied and contributed to advance of theory.

Symbols

c	distribution coefficient
E_{dis}	dispersion energy
I	nuclear spin
P_2	second Legendre polynomial
r	interatomic separation
R_1	longitudinal relaxation rate
T_0	reference temperature
T_1	spin–lattice relaxation time
$V(r)$	potential function for Xe–Xe pair interactions
α	isobaric thermal expansion coefficient
δ	chemical shift
$\Delta\sigma_d$	shielding anisotropy of xenon
ρ	density
σ_0	shielding constant of reference gas
σ_a	magnetic anisotropy shielding constant
σ_b	bulk susceptibility shielding constant
σ_{exp}	experimental shielding constant
σ_E	permanent electric dipole shielding constant
σ_M	paramagnetic species shielding constant
σ_S	surface induced shielding constant
σ_{SAS}	strong absorption sites shielding constant
σ_W	van der Waals interaction shielding constant
σ_{Xe}	shielding constant of xenon gas
τ_M	mixing time
ϕ	angle between external magnetic field and liquid–crystal director

Nuclear magnetic resonance experiments were originally planned for measuring nuclear magnetic moments. This explains why such exotic nuclei as ^{129}Xe (spin- $\frac{1}{2}$) and ^{131}Xe (spin- $\frac{3}{2}$) were the subjects of NMR investigations already as early as 1951, only about 5 years after the first successful NMR experiments at Harvard and Stanford. In the 1960s and 1970s, researchers were mostly interested in performing shielding and relaxation experiments of the two xenon isotopes (as well as of the other noble gas

nuclei: ^3He , ^{21}Ne and ^{83}Kr) in gas, liquid and solid states. The expansion of xenon NMR spectroscopy started in the early 1980s when it was proposed that the physical properties of zeolites and clathrates, and in general, of porous solids, could be characterized by adsorbing xenon to the sample and recording the ^{129}Xe NMR spectrum. Since then, xenon NMR has been applied to derive information on (besides porous solids) various isotropic liquids and liquid mixtures, liquid crystals, proteins and membranes, myoglobin and haemoglobin, and polymers. The finding that ^{129}Xe can be spin-polarized by optical pumping, leading to a sensitivity increase up to a factor of 10^5 , has widened the field of application to low surface area solids, human blood and perfused tissue, and imaging of organs of small animals, and even of humans.

Properties of the Nuclei

Xenon possesses nine stable isotopes, but only two of them, ^{129}Xe and ^{131}Xe , have a nonzero spin necessary for magnetic resonance. NMR properties of these isotopes are collected in **Table 1**. Xenon being a monatomic gas, the ^{129}Xe and ^{131}Xe NMR spectra recorded in isotropic solutions, for example, consist of a single resonance line. In anisotropic environments with nonzero static electric field gradient (EFG), the ^{131}Xe NMR spectrum is a triplet. Despite this simplicity, the spectra provide much information on the environment into which the xenon is introduced. This is due to the fact that the xenon shielding is extremely sensitive to the changes taking place in its local environment. Furthermore, as xenon is very inert it does not disturb the system into which it is taken. In the literature, the change of the shielding of atomic xenon, arising from bulk and local effects, is often called the chemical shift. This is somewhat misleading. However, in this article chemical shift ($\delta = \sigma_0 - \sigma_{\text{Xe}}$, σ_0 and σ_{Xe} being the shielding of the reference gas, usually free xenon gas, and of xenon introduced into the

Table 1 Properties of the NMR active xenon Isotopes ^{129}Xe and ^{131}Xe

^aAt the magnetic field $B_0 = 9.39 \text{ T}$.^bAbsolute sensitivity (product of the relative sensitivity and natural abundance) with respect to the ^{13}C isotope.

environment under study, respectively) and shielding ($\sigma_{\text{Xe}} - \sigma_0 = -\delta$) are used in parallel.

The 32-fold sensitivity of ^{129}Xe compared to ^{13}C makes it an easy nucleus for NMR detection; the spectrum may be obtained on a single pulse from samples with $\sim 1 \text{ atm}$ or higher pressure of gas. This is a great advantage because often the spin-lattice relaxation time, T_1 is long, up to hundreds of seconds in solutions and up to over 100 min in the gas phase. In many applications, relaxation agents can be utilized to shorten T_1 . The ^{131}Xe isotope possesses an electric quadrupole moment and thus its spin-lattice relaxation is dominated by the quadrupole interaction; the T_1 values are in the millisecond range, allowing a relatively fast pulse repetition in accumulation.

A drastic improvement in the NMR sensitivity of ^{129}Xe can be achieved by the optical pumping method. In a conventional NMR experiment, the nuclear magnetization arises from the population difference due to Boltzmann distribution between energy states. For example, for ^{129}Xe at the magnetic field of 9.4 T and at thermal equilibrium at $T = 300 \text{ K}$, the relative population difference between the $m = -\frac{1}{2}$ and $m = +\frac{1}{2}$ states is $9 \times 10^{-6} = 9 \text{ ppm}$. When applying optical pumping with a high-powered laser, this figure can be increased up to > 0.3 , i.e. the magnetization increases by a factor of $\sim 3 \times 10^5$. This increase is performed by placing xenon and nitrogen gas together with alkali-metal vapour (usually rubidium) in a glass cell and illuminating by circularly polarized laser light with a wavelength of 749.7 nm. During binary collisions, spin polarization is transferred from alkali-metal atoms to xenon atoms.

Xenon in Gases

The shielding of pure xenon gas is often expressed as a virial expansion

$$\sigma(\rho, T) = \sigma_0 + \sigma_1(T)\rho + \sigma_2(T)\rho^2 + \sigma_3(T)\rho^3 \quad [1]$$

where σ_0 is the shielding constant of the atom *in vacuo*, ρ is density (given in amagat, the density of xenon under standard conditions at 298 K, $\sim 2.5 \times 10^{19} \text{ atoms cm}^{-3}$), and for the virial coefficients the following values have been reported (at 298 K): $\sigma_1 = -0.548 \pm 0.004 \text{ ppm amagat}^{-1}$, $\sigma_2 = (-0.17 \pm 0.02) \times 10^{-3} \text{ ppm amagat}^{-2}$,

and $\sigma_3 = (0.16 \pm 0.01) \times 10^{-5} \text{ ppm amagat}^{-3}$. The coefficients σ_1 , σ_2 and σ_3 arise from two-, three- and four-body interactions, respectively. At low densities the shielding constant depends linearly on density, whereas at high pressures many-body collisions become important as well and cause deviation from linearity. The second virial coefficient arises from the Xe-Xe pair interactions (with the potential $V(r)$, r is the interatomic separation) and can be presented in the form

$$\sigma_1(T) = 4\pi \int_0^\infty \sigma(r) \exp[-V(r)/kT] r^2 dr \quad [2]$$

When xenon is mixed with another gas, G, the collisions Xe-G also contribute to the ^{129}Xe shielding. If only binary collisions are considered to be important, the shielding of xenon is given by

$$\sigma_{\text{exp}} = \sigma_0 + \sigma_1(\text{Xe-Xe})\rho_{\text{Xe}} + \sigma_1(\text{Xe-G})\rho_{\text{G}} \quad [3]$$

where ρ_{Xe} and ρ_{G} are the densities of Xe and G, respectively. Once $\sigma_1(\text{Xe-Xe})$ is determined in pure xenon gas, the $\sigma_1(\text{Xe-G})$ term can be solved from eqn [3]. Mixtures of xenon with other noble gases as well as with some small molecules, such as CO, N₂, O₂, CO₂, CH₄, SiF₄, SF₆, etc., have been studied. The very recent coupled Hartree-Fock calculations with gauge-including atomic orbitals on the shielding surfaces of the Xe-CO₂, Xe-N₂ and Xe-CO systems predict second virial coefficients in fair agreement with the corresponding experimental ones. The calculations revealed the shielding surfaces to be highly anisotropic.

In the early days of ^{129}Xe NMR, the spin-lattice relaxation time was assessed to be very long, and therefore a paramagnetic substance (Fe₂O₃) was used to shorten it in the first NMR experiments. The estimate of long T_1 was based on the dipolar interaction between two nuclei when they collide with each other. This model leads to the relaxation rate, $R_1 = 1/T_1$, which is inversely proportional to the mean collision time. Another interaction, more effective than the dipolar one, is the spin-rotation interaction, in which the nuclear spin couples with the angular momentum of a transient diatomic molecule formed during the collision. This model accounts for the experimental finding of R_1 being linearly dependent on the gas density; $R_1 = (5.0 \pm 0.5) \times 10^{-5} \rho$, where R_1 is given in s⁻¹ and ρ in amagats. The T_1 value determined in hyperpolarized ^{129}Xe

has been found to be dependent upon the magnetic field strength: 155 min (gas pressure 790 torr) and 185 min (896 torr) at 2.0 T, and 66 min (790 torr) and 88 min (896 torr) at 7.05 T, experimental error being $\sim 5\%$ and temperature 20 °C. The slight variation of T_1 at a constant magnetic field is assumed to arise from differences in the cell wall structure, whereas the field dependence was interpreted as a consequence of the less effective wall interaction at the higher magnetic field where the nuclear precession frequency is also higher.

The spin–lattice relaxation of the ^{131}Xe isotope is predominantly due to the interaction of the nuclear electric quadrupole moment with the electric field gradient (EFG) induced during binary collisions. Experiments have shown that also in this case the relaxation rate is linearly dependent upon the density: $R_1 = 0.039 \rho$, where R_1 is in s^{-1} and ρ in amagats. Theory has given a similar relation with a proportionality coefficient of 0.046.

Xenon as a Probe in Liquid and Solid Environments

Isotropic Liquids

For xenon dissolved in an isotropic liquid, the solvent effect on the shielding, σ_m , can be represented as

$$\sigma_m = \sigma_{\text{exp}} - \sigma_0 - \sigma_b = \sigma_a + \sigma_w + \sigma_E \quad [4]$$

where σ_{exp} is the experimental shielding constant, σ_0 is the shielding in the free atom (obtained by extrapolation of σ_{Xe} to zero pressure), σ_b arises from bulk susceptibility, σ_a from the magnetic anisotropy of the nearest neighbouring solvent molecules, σ_w from the van der Waals interactions, and σ_E is the shielding contribution caused by the permanent electric dipole of the solvent. Solvent-induced change of the ^{129}Xe shielding is about 250 ppm, as can be seen from Table 2. On the other hand, the ^{129}Xe gas-to-solution shifts, i.e. the change of the shielding compared to the shielding of free xenon, are over 330 ppm.

Various models have been developed for explaining the solvent-induced changes in the ^{129}Xe shielding. For example, it has been proposed, based on the reaction field theory of Onsager, that the medium shift is proportional to the function $f(n) = [(n^2 - 1)/(2n^2 + 1)]^2$ (this is called the van der Waals continuum model), where n is the refractive index of the solvent. Part of the experimental data indeed follows this relation, but most does not. An alternative model is provided with the pair interaction structureless approximation (PISA). The xenon–solvent dispersion energy, E_{dis} , calculated on this approximation is found to correlate better with the ^{129}Xe medium shift than $f(n)$.

One possible approach to gain insight into the solvent effects is to perform group contribution analysis. ^{129}Xe gas-to-solution shifts have been determined for pure

n-alkanes, *n*-alkyl alcohols, *n*-alkyl carboxylic acids, di-*n*-alkyl ketones and cycloalkanes, and in solutions of lauric acid in *n*-heptane. It was found that the medium shifts corrected for solvent density are linearly dependent on the number of carbon atoms, except for the shortest members of the series of linear solvents (see Figure 1). Not only the structure of the environment but also temperature affects the ^{129}Xe shielding significantly. For example, in CD_3CN the shielding increases with increasing temperature (i.e. with decreasing density) at the rate of 0.30 ppm K^{-1} . This is 33 Hz K^{-1} at the magnetic

field of 9.4 T. The position of the xenon resonance can be determined often with accuracy to better than 0.5 Hz, and consequently, ^{129}Xe shielding provides a good basis for a thermometer; accuracy may even be 0.02 K. A modified continuum model of van der Waals shifts has been presented to include also the effect of temperature. However, this model predicts temperature shifts in reasonable agreement with experiments only for the *n*-alkanes.

Although xenon NMR has been applied fairly widely to study physical properties of various materials, surprisingly little attention had been paid to its relaxation. The situation however, changed with the application of hyperpolarized ^{129}Xe ; the longitudinal hyperpolarized magnetization decays with the spin–lattice relaxation time, T_1 . The relaxation mechanisms of the ^{129}Xe isotope are exclusively due to interparticle (xenon–solute molecule) interactions. In pure xenon gas, the relaxation mechanism has been proposed to arise from spin–rotation (SR) coupling during atomic collisions or during the transient existence of diatomic molecules. The SR interaction may also partly explain the relaxation of ^{129}Xe in benzene; the xenon atom is located on the C_6 symmetry axis of benzene with a binding energy of 10.4 kJ mol^{-1} . The dominating interaction in protonated solvents, however, is the $^{129}\text{Xe}^{-1}\text{H}$ dipolar interaction; in benzene its contribution is over 50% and in cyclohexane over 90% of the total relaxation rate, $R_1 = 1/T_1$. The T_1 ranges from $\sim 70 \text{ s}$ to $\sim 1000 \text{ s}$ for xenon in typical isotropic solvents. In blood cells and plasma, the T_1 is 4.5 s and 9 s, respectively, whereas in blood foam it is 21 s (oxygenated) and 40 s (deoxygenated).

The relaxation of the quadrupolar ^{131}Xe nucleus is predominantly due to the interaction between the nuclear electric quadrupole moment and the fluctuating EFG at the nuclear site. The origin of the EFG contributing in a solution is, however, still partly an open question. Various models, both electrostatic and electronic, have been developed. The electrostatic models assume the EFG to be due to solvent molecules represented by point charges, point dipoles or quadrupoles, or a dielectric continuum. In the electronic approach, EFG is considered to be a consequence of the deformation of the spherical electron distribution of ^{131}Xe . The deformation arises from the collisions between xenon and solvent molecules. It is obvious (evidence is provided, for example, by ^{131}Xe NMR experiments in liquid-crystal solutions, and by first principles calculations) that neither of these approaches alone is sufficient. In typical isotropic solvents, the ^{131}Xe T_1 ranges from $\sim 4 \text{ ms}$ to $\sim 40 \text{ ms}$.

Liquid Crystals

Thermotropic liquid crystals (LC) are anisotropic liquids that possess a mesophase (a phase with crystal and liquid properties) within a certain temperature range. In a

spectrometer magnet, LC molecules tend to orient to a common direction which defines the director of the liquid crystal. The director may orient either along the external magnetic field or perpendicular to it, depending upon the sign of the anisotropy of the diamagnetic susceptibility. When xenon is dissolved in a liquid crystal and its ^{129}Xe NMR spectrum is recorded at variable temperatures, a series of spectra, as shown in Figure 2, may be obtained. This kind of experiment provides information on phase transition, isobaric thermal expansion coefficient, liquid–crystal orientational order parameters and anisotropy of the ^{129}Xe shielding tensor ($\Delta\sigma_d$). The latter property arises from the fact that in a mesophase, the originally spherical electron cloud of xenon is deformed leading to an axially symmetric shielding tensor with nonzero $\Delta\sigma_d$. The above-mentioned quantities can be derived from eqn [5] by least-squares fitting:

$$\begin{aligned} \sigma_{\text{exp}}(T) - \sigma_0 = & [1 - \alpha(T - T_0)] \{ \sigma_d [1 + 2c\tau_1^2(T)] \\ & + (2/3)P_2(\cos\phi)\Delta\sigma_d[S(T) \\ & + 2c\sigma_1(T)\tau_1(T)] \} \end{aligned} \quad [5]$$

where $\sigma_{\text{exp}}(T) - \sigma_0$ is the shielding difference for xenon in liquid–crystalline and gaseous phases, α is the isobaric

Figure 2 ^{129}Xe NMR spectra of natural xenon gas in a binary mixture of the Merck S1114 and EBBA liquid crystals. The shielding (in ppm) is referenced to that at 360 K. On the right are shown the various phases: I (isotropic), N (nematic), S_A (smectic A), and S_B (smectic B). Adapted with permission of Gordon and Breach Publishers from Jokisaari J, Diehl P, and Muenster O (1990) *Molecular Crystals and Liquid Crystals* 188: 189–196.

thermal expansion coefficient, T_0 is the reference temperature (for example, the isotropic–nematic or nematic–smectic A phase transition temperature), σ_d and $\Delta\sigma_d$ are the shielding constant and shielding anisotropy of xenon, $S(T)$, $\sigma_1(T)$ and $\tau_1 T$ are the conventional order parameter, translational–orientational order parameter and translational order parameter (the last two are present only in smectic phases), respectively, P_2 is the second Legendre polynomial, and ϕ is the angle between the external magnetic field and the liquid-crystal director, and the coefficient c describes how much the positional distribution function deviates from a uniform distribution.

As mentioned above, the ^{131}Xe nucleus possesses an electric quadrupole moment. In a liquid–crystalline solution the quadrupole moment interacts with the EFG at the nuclear site, and consequently, instead of a single resonance peak detectable in isotropic phases, a triplet with theoretical relative intensities of 3:4:3 is observed. (Generally, the multiplet consists of $2I$ resonance lines, where I is the spin of the nucleus.) An example is given in **Figure 3**. The quadrupole splitting, i.e. the separation of the resonance peaks in a spectrum, can be used for determining external EFGs, i.e. EFGs arising from the electric multipoles of LC molecules, EFGs arising from the deformation of the electron cloud of xenon when it collides with LC molecules and LC orientational order parameters.

Polymers

The physical and mechanical properties of polymeric systems are connected with their solid state morphology. NMR spectroscopy of the nuclear spins attached to a

polymeric system is a very applicable means to gain insight into the microstructure as well as into the dynamics of the system. An alternative way is to make use of a probe, such as a xenon atom, which diffuses over the environment and gives information on the microscopic heterogeneity.

Since the xenon shielding is sensitive to the density of the surrounding medium, one may expect that it is affected by the glass transition of an amorphous polymer. Indeed this is the case, but, however, a more distinct change can be detected in the ^{129}Xe line width, as shown for poly(ethyl methacrylate) in **Figure 4**. ^{129}Xe NMR has proven to be particularly useful in studies of polymer blends whose components possess almost identical glass transition temperatures. Namely, for a phase-separated two-component blend, the ^{129}Xe spectrum consists of two resonance signals, while the homogeneous morphology of a miscible blend yields a single resonance. The application of thermal analysis techniques is restricted by the fact that the different glass transitions can only be detected if they differ at least by 20 K.

When xenon is adsorbed, for example, into a solid EPDM rubber (a terpolymer composed of ethylene, propylene and ethylidene norbornene) at least four distinct ^{129}Xe resonance signals can be observed indicating the presence of physically distinct domains; the intensity ratios may be used for the determination of the size of the domains, whereas the shielding differences reveal the variation of the density in the domains. When the rubber is cross-linked, the spectrum is clearly different from the one before cross-linking. As **Figure 5** shows, the cross-linking leads to the disappearance of the signal corresponding to the highest shielding of ^{129}Xe , i.e. the largest amorphous voids. This is consistent with the fact that cross-linking produces a more condensed polymer matrix.

One possibility for investigating microheterogeneity in polymers with the xenon probe is to apply the cross-polarization (CP) technique, in which polarization is

Figure 3 The ^{131}Xe triplet of xenon in the thermotropic Merck ZLI1167 liquid crystal. The frequency separation of the two outmost peaks is ~ 56 kHz. The intensity ratios are distorted because of experimental instabilities. Run parameters: ^{131}Xe resonance frequency 49.218 MHz ($B_0 = 14.1$ T), acquisition time ~ 7 min, $T = 325$ K. (Unpublished data from this laboratory.)

Figure 4 (a) ^{129}Xe chemical shift, and (b) ^{129}Xe line width at 24.79 MHz as a function of temperature for xenon adsorbed in poly(ethyl methacrylate), the glass temperature, T_g is 65°C . Figure 5 ^{129}Xe NMR spectra of xenon adsorbed in solid EPDM: (a) before, and (b) after crosslinking. Note: the scale is the chemical shift scale, which is opposite to the shielding scale. Adapted with permission of Springer-Verlag from Kennedy GJ (1990) *Polymer Bulletin* 23: 605–606.

transferred from polymer protons to ^{129}Xe . The necessary condition for ^1H – ^{129}Xe CP is for the xenon atom to be trapped long enough near a proton for the dipolar coupling between the nuclei to be effective. **Figure 6** displays the normal single-pulse ^{129}Xe NMR spectrum, together with the ^1H – ^{129}Xe CP spectrum of xenon in a polymer blend of a copolymer (a mixture of 2/3 polyethylene, PE, and 1/3 polypropylene, PP) dispersed in a polymer matrix. The latter spectrum consists of a single resonance peak arising from xenon in the PP matrix where the translational mobility of the xenon atom is slow enough in order not to interrupt the dipolar coupling between the nuclei. Because of the CP between the PP protons and xenon adsorbed in the PP matrix, it is possible to obtain a correlation spectrum between the two spins, making it possible to identify the protons involved in the polarization transfer.

Figure 6 (Top) The conventional single-pulse ^{129}Xe NMR spectrum and (bottom) the ^1H – ^{129}Xe CP spectrum of xenon in a polymer blend. The mixing time in the CP experiment was 3 ms. The signal at 0 ppm arises from free xenon gas, the signal at 216 ppm from xenon in copolymer and the signal at 226 ppm from xenon in PP. Note: the scale is the chemical shift scale, which is opposite to the shielding scale. Adapted with permission of Elsevier Science Ltd from Mansfeld M and Veeman WS (1994) *Chemical Physics Letters* 222: 422–424.

The efficiency of the polarization transfer depends upon the internuclear distance according to r^{-6} , and consequently, it is restricted to the nearest-neighbour protons of xenon. Thus CP experiments yield information only on the spatial proximity of distinguishable domains in a polymer. A much wider range of distance can be covered by two-dimensional (2D) exchange spectroscopy (EXSY). Its application is most useful in cases where the exchange rate of xenon between domains is slow compared to the chemical shift difference, and separate resonance signals from xenon in each domain can be observed. **Figure 7** displays results for ^{129}Xe 2D EXSY experiments on a model blend system of poly vinyl chloride (PVC) and poly vinyl methyl ether (PVME). The system consists of thin alternating layers (thickness 2–6 μm) of the two polymers. The EXSY experiments were performed with two mixing times, 0.8 s and 8 s. It is seen that during the shorter mixing time, xenon samples all the local environments in the PVC domains (this is indicated by the round shape of the diagonal peak), whereas no exchange between the PVC and PVME is taking place (there is no cross-peak in the spectrum). In contrast, during the mixing time of 8 s, exchange between the two phases is also seen.

Zeolites, Molecular Sieves and Clathrates

Most attention has been drawn to the application of ^{129}Xe NMR to studies of zeolites, molecular sieves and clathrates. The main goal is to derive information on the size and shape of the pores of unknown structure through

Figure 7 ^{129}Xe spectrum (a), and ^{129}Xe 2D EXSY spectra (b and c) of xenon in the PVC/PVME model blend. τ_m is the mixing time. The insets show contour plots of the same data. Adapted with permission of Elsevier Science Ltd from Tomaselli M, Meier BH, Robyr P, Suter UW, and Ernst RR (1993) *Chemical Physics Letters* 205: 145–152.

the ^{129}Xe shielding measurements. In principle this information is available but not very straightforwardly since the xenon shielding is affected not only by the two factors but also by xenon–xenon collisions, and the presence of strong absorption sites (SAS), paramagnetic species and adsorbed molecules, etc. The experimental shielding of xenon in zeolites and molecular sieves is usually represented in the form

$$\sigma_{\text{exp}} = \sigma_0 + \sigma_S + \sigma_{\text{Xe}} + \sigma_{\text{SAS}} + \sigma_E + \sigma_M \quad [6]$$

where σ_0 is the shielding of the reference (usually a zero pressure gas), σ_S arises from the interaction of xenon with

Figure 8 Dependence of the ^{129}Xe chemical shift (negative shielding) upon the number of xenon atoms adsorbed per gram of zeolite. Fraissard J (1996) In: Grant DM and Harris RK (eds.) *Encyclopedia of Nuclear Magnetic Resonance Spectroscopy*, Vol. 5, pp. 3058–3064. Chichester: Wiley © John Wiley & Sons Limited. Reproduced with permission.

the pore walls, $\sigma_{\text{Xe}} = \sigma_{\text{XeXe}}\rho_{\text{Xe}}$ is the shielding contribution of the xenon–xenon collisions, σ_{SAS} stems from Xe interaction with strong adsorption sites, σ_E in turn takes into account electric field effects (due to charge-compensating cations) and σ_M is the contribution of paramagnetic species.

Figure 8 shows the ^{129}Xe chemical shift as a function of the number of xenon atoms in different zeolites. The shielding values ($= -\delta$), obtained by extrapolation to zero xenon number, range from ~ -110 ppm to ~ -60 ppm (in fact, in mordenite, which is not shown in the figure, it goes down to -250 ppm), indicating the sensitivity of xenon shielding to zeolite structure.

No comprehensive theory exists for interpreting the experimental Xe shielding results in porous materials, although very significant progress in this direction has taken place recently; in particular, simulation calculations have improved our knowledge. In order to develop the method to a level giving as diversified information as possible of the shape and size of void space (and possibly cation distribution), it is important to investigate systems with varying properties and well-defined structure. The most simple systems are zeolites without charge compensating cations, and paramagnetic species when the two last shielding contributions in eqn [6] can be

neglected. Very illustrative examples are the siliceous zeolite Si-ZSM-12 and molecular sieve $\text{AlPO}_4\text{-11}$. In the first approximation, both possess 1D channels with elliptical cross section. A closer inspection, however, reveals that the structure is more complex, consisting of series of cells, which have to be taken into account when interpreting experimental shielding data. The static ^{129}Xe spectrum in these two systems is a CSA (chemical shift anisotropy) powder pattern whose shape changes continuously from axially symmetric to asymmetric upon the xenon loading, as shown in **Figure 9**. Powder-like spectra have been observed for xenon only in a few zeolites. This may partly be due to misinterpretation of observed, slightly asymmetric line shapes; the xenon shielding is significantly affected by magnetic field inhomogeneity as well as by temperature gradients and fluctuations, and thus the CSA contribution, when small, has been masked by these instabilities during spectral recordings. The line shapes for xenon in Si-ZSM-12 and $\text{AlPO}_4\text{-11}$ have been explained by a dynamic model. In this model the shielding tensor is a dynamic,

Figure 9 Static ^{129}Xe NMR spectra of xenon adsorbed in Si-ZSM-12 zeolite for different loading levels (xenon atoms per unit cell, Xe/u.c.). All spectra were recorded at 295 K. population-weighted average of tensors corresponding to three sites at which xenon has 0, 1 or 2 neighbouring xenons, and xenon samples rapidly fill the space available to it. When the elements of the shielding tensor are presented as a function of xenon loading, a linear dependence is observed at low loadings and thus the extrapolation to zero loading is straightforward and gives the shielding tensor elements corresponding to xenon with no neighbouring xenon atom.

The averaging of the xenon shielding tensor, and consequently, the derivation of structure information from the ^{129}Xe shielding data, necessitates the knowledge of xenon dynamics. (One should emphasize here also that the dynamics of the zeolite framework affects significantly the averaging process. This is a consequence of the decrease of the effective potential barrier to intercellular jumps of xenon.) The observed line shape and shielding are averages over the shielding tensors of xenon sampling intra-cage volume and exchanging between cages, i.e. the mobility of xenon. For the first time, a CSA powder pattern was observed for xenon trapped in a clathrate where xenon is truly immobile. Xenon dynamics is available through spin-lattice relaxation time and diffusion measurements and 2D EXSY experiments.

2D EXSY has been applied, for example, to study xenon dynamics in the NaA zeolite whose structure is composed of large α -cages (inner diameter approximately 11.4 Å) and smaller β -cages (6.6 Å). At elevated temperatures and pressures the Xe atoms are distributed among the α -cages. This is seen in the ^{129}Xe 1D NMR spectrum which displays several distinct resonance signals (see **Figure 10**); xenon shielding decreases with increasing number of atoms in a cage. **Figure 10** also shows the results of the 2D EXSY experiments performed with three different mixing times. The emergence of cross-peaks arises from intercage motion of xenon during the mixing time. Performing the experiment at variable temperatures allows for the derivation of the rates of intercage motion as well as the adsorption and activation energies of the xenon atoms.

Applications of Laser-Polarized Xenon

The ^{129}Xe magnetization can be enhanced compared to the thermal equilibrium magnetization by a factor of $\sim 10^5$ by utilization of optical pumping and spin-exchange between xenon and alkali-metal atoms. The resulting state is a nonequilibrium state, and the magnetization is often called hyperpolarized magnetization. One has to take into account the following facts when performing NMR experiments: (i) the hyperpolarized spins decay towards thermal equilibrium with the spin-lattice relaxation time T_1 , and thus the hyperpolarization cannot be recovered by waiting for thermal

Figure 10 (a) ^{129}Xe 1D NMR spectrum (on top of each peak is shown the number of Xe atoms in the cage) and (b) ^{129}Xe 2D EXSY spectra of xenon adsorbed in NaA zeolite at 523 K and 30 atm (1 atm = 101 325 Pa). The mixing times are: 0.2, 0.5 and 2.0 s as shown. Adapted with permission of Elsevier Science Ltd from Larsen RG, Shore J, Schmidt-Rohr K et al. (1993) *Chemical Physics Letters* 214: 220–226.

equilibrium, (ii) when a radiofrequency θ pulse is applied to the spin systems, the longitudinal hyperpolarized magnetization decreases by $\cos \theta$. On the other hand, when applying repeated pulses the pulse repetition time can be short because there is no need to wait for the spin system to return to thermal equilibrium. In most applications the ^{129}Xe NMR spectrum of hyperpolarized xenon can be obtained on a single pulse. It is also possible to apply continuously flowing hyperpolarized ^{129}Xe .

Hyperpolarized ^{129}Xe can be utilized in two ways: firstly, by observing directly the ^{129}Xe NMR spectrum of xenon introduced to the environment under study, and secondly, by transferring hyperpolarization from xenon to other nuclei and recording their spectra. The polarization transfer takes place through cross-relaxation between spins without the need for irradiation of the spins. This technique has been denoted SPINOE (spin polarization induced nuclear Overhauser effect). The

Figure 11 Evolution of the ^1H spin magnetization of PEO (poly-ethylene oxide)-coated Aerosil1130 as a function of time after exposure of the surface to hyperpolarized ^{129}Xe . The initial Xe pressure is 160 torr and the sample temperature is 130 K for positive SPINOE ($\bullet$) and 125 K for negative SPINOE ($\circ$). The inset displays two single-shot ^1H spectra from a negative SPINOE run, one taken at the Boltzmann equilibrium for the unpolarized sample (positive peak) and the other taken at the time t_0 , when the negative SPINOE enhancement has reached its maximum absolute value. Adapted with permission from R  m T, Appelt S, Seydoux R, Hahn EL, and Pines A (1997) *Physical Review B* 55: 11604–11610.

SPINOE may be either positive or negative depending upon whether right or left circularly polarized light is applied.

When hyperpolarized ^{129}Xe gas is dissolved, for example, into benzene, the ^1H NMR signal is enhanced because of SPINOE. This finding opened up new views for deriving information, for example, on Xe–protein interactions as well as on blood and other biological systems. The very high sensitivity of hyperpolarized ^{129}Xe makes it possible to investigate also low surface area ($1\text{--}10\text{ m}^2\text{ g}^{-1}$) nonporous solids which otherwise, due to the low inherent sensitivity of NMR, are difficult if not impossible to investigate. On the other hand, magnetization transfer from hyperpolarized ^{129}Xe to other nuclei, e.g. ^1H and ^{13}C on a surface, allows for the direct observation of the magnetic resonances of these isotopes. Experiments have shown that enhancement of proton magnetization even by a factor of 20 may be achieved at low temperatures. The enhancement is more

pronounced at low temperatures because of decreasing mobility of xenon atoms. An example of the ^1H magnetization enhancement is given in Figure 11.

Clathrates were the first systems investigated by ^{129}Xe NMR of natural xenon gas. The xenon atom is of the same size and shape as methane and it also forms a clathrate hydrate with water. The xenon shielding is much more sensitive (by a factor of about 30) than the ^{13}C shielding of methane to the changes taking place in the structure of their environment. The use of hyperpolarized ^{129}Xe allows the investigation of large and small cages of clathrate hydrate; two distinct resonance signals are seen in the spectrum as shown in Figure 12. A number of studies of porosity and flow of gases in zeolites, clathrates and nanotubes has been made using hyperpolarized xenon and ^{129}Xe NMR spectroscopy. Much interest has been drawn to the application of hyperpolarized ^{129}Xe to materials, and in particular, to medical imaging (xenon gas is a safe general anaesthetic) and to spectroscopy in blood systems and in tissue, specifically the heart, lungs, brain and other organs. For example, the technique has been used to obtain human lung images. In this case, $\sim 0.5\text{ L}$ of hyperpolarized ^{129}Xe is needed, necessitating higher power (100–120 W) lasers.

The approach has been used to study a wide range of effects in biomedicine, and several hyperpolarized gases, not only xenon, have found a steadily increasing range of applications, particularly in MRI. They can be thought of as a new type of MR contrast agent. Alternatively, they can improve the temporal resolution of a measurement process because of the increased sensitivity through polarization transfer to other nuclear species such as ^1H .

Figure 12 The ^{129}Xe NMR spectra of the formation of a xenon clathrate hydrate at 233 K and time t after admission of the xenon to the powdered ice sample. The signal at 160 ppm is attributed to xenon in the large tetrakaidecahedral cages and the one at 240 ppm to xenon in the smaller dodecahedral cages. ^aIn some cases, the range of experimental values is given.

Figure 13 ^{129}Xe NMR chemical shifts of a few selected xenon compounds. Adapted with permission from Jameson C (1987) The noble gases. In: Mason J (ed.) *Multinuclear NMR*, Chapter 8, pp. 463–477. New York: Plenum Press.

Finally, because of the increased sensitivity, the use of such methods opens up the possibility of low low-field MRI, perhaps, using the earth's magnetic field.

Xenon Compounds

Xenon is known to covalently bind to fluorine, oxygen, nitrogen, carbon and to itself. In such circumstances, ^{129}Xe exhibits a large range of chemical shifts, about 7500 ppm. **Figure 13** displays chemical shifts of some selected xenon compounds with different oxidation states. Also the ^{129}Xe shielding anisotropy may be large. For example, the theoretical estimate of the shielding anisotropy for XeF_2 is 5125–7185 ppm, for XeF_4 it is 3940 ppm and for XeOF_4 it is 365–1500 ppm. Spin–lattice

relaxation time measurements have given an anisotropy of ~ 4700 ppm for XeF_2 . In this particular case, the relaxation is dominated by the CSA and SR interactions and the T_1 values range from 150 to 430 ms depending upon magnetic field strength (CSA interaction depends upon the square of the magnetic flux density) and temperature (SR interaction depends linearly upon temperature). In general, the ^{129}Xe T_1 of various species in solution varies between 285 and 780 ms. Thus the relaxation is much faster than that of atomic xenon, and renders possible fast repetition rates in data accumulation. The one-bond spin–spin couplings of xenon with ^{19}F are relatively large and include a sizable relativistic contribution. The change of the absolute value of $^1J(^{129}\text{Xe}-^{19}\text{F})$ can be used as a diagnostic tool to confirm the formal oxidation number of xenon as the coupling

decreases in the order: Xe(II) > Xe(IV) > Xe(VI). Xenon couplings to other nuclei are smaller. No absolute sign determination has been made for any of the couplings to xenon. **Table 3** shows absolute spin–spin coupling values of some selected xenon compounds.

Introduction

The task of an X-ray absorption spectrometer is the precise and accurate measurement of the linear X-ray absorption coefficient of a substance. A principal use of such spectrometers is the measurement of X-ray absorption fine structure (XAFS) spectra of solids, liquids, and molecular gases. XAFS consists of modulations in the X-ray absorption coefficient in the vicinity of an X-ray absorption edge, which may extend more than one KeV beyond the edge. Applications and theory of X-ray absorption spectroscopy are covered elsewhere in this volume. This article is directed primarily to instrumental requirements for X-ray absorption spectroscopy over the energy range from several KeV X-ray photon energy to approximately 100 KeV, with emphasis on synchrotron radiation-based instruments.

Absorption, Fluorescence, and Fluorescence Excitation Spectra

In the simplest case, the X-ray absorption coefficient (μ) of a homogeneous sample of thickness x is given by

$$\frac{I}{I_0} = \exp[-\mu(\varepsilon)x]$$

where I_0 and I respectively are the incident and transmitted X-ray intensities at X-ray photon energy ε . An

analogous quantity in optical absorption spectroscopy is the product of the molar extinction coefficient and the concentration.

X-ray *absorption* spectrometers are distinct from X-ray *fluorescence* spectrometers (often referred to as ‘X-ray spectrometers’), which measure the intensity of fluorescence radiation emitted by atoms in a specimen following their excitation by high energy photons, charged particle beams, or other interactions. X-ray fluorescence spectrometers are primarily used for measuring the elemental composition of samples, or measuring shifts in energy of fluorescence, to obtain chemical information about a sample.

A principal use of X-ray absorption spectrometers is in the measurement of X-ray absorption fine structure (XAFS) spectra, which provide quantitative information on the local structural and chemical environment within the region several ångströms around selected atomic species in a sample. Absorption and fluorescence spectroscopies are complementary, and both can be used for spatially resolved spectroscopic mapping of samples. Fluorescence spectrometers also have considerable applicability for determining elemental composition in astrophysical research, planetary sciences, and numerous other areas.

There are many situations in which the X-ray absorption spectrum is most easily measured (indirectly) by monitoring the fluorescence produced following absorption of X-rays. One measures variations in the fluorescence intensity of a particular atomic species as the energy of incident photons is varied over an absorption edge of a selected element. This ‘fluorescence excitation spectrum’, distinct from the fluorescence spectrum, provides an indirect measurement of the X-ray absorption coefficient, albeit one that is subject to several well-known instrumental effects. If care is taken in sample preparation, systematic errors can be minimized. Fluorescence detection is the method of choice for dilute systems, because it provides an improved signal-to-noise ratio.

X-Ray Absorption Spectra

Over the range from several KeV to 100 KeV, X-ray photons propagating through a sample are absorbed,

scattered without loss of energy (elastic scattering), or scattered with loss of energy (inelastic scattering). X-rays require energies in excess of one MeV for positron-electron pair production to occur.

Cross sections vary significantly as a function of energy, as shown in **Figure 1a** and **b**. Absorption cross sections between the absorption edges decrease approximately as $1/\epsilon^3$.

Absolute and Relative Measurements

Although it is essential to use samples of appropriate thickness and concentration in XAFS experiments, in practice it is seldom necessary to precisely determine the

absolute absorption coefficient. The quantities of interest (e.g. inter-atomic bond lengths) are intrinsic to the material, while the absolute absorption coefficient depends on the thickness of the specimen, concentration of the element of interest, and other irrelevant factors. The standard methods of XAFS analysis treat the data in such a way that the structural parameters ultimately determined are invariant with respect to change of multiplicative scale factors, and additive background, provided it is a sufficiently smooth function of energy. To the extent that the X-ray scattering cross sections vary slowly with energy, or are negligible compared to the photoelectric cross section, they do not affect the structure determination. It should be noted, however, that both the elastic and inelastic scattering cross sections do have small contributions that vary near absorption edges and may need to be accounted for in some circumstances.

For some purposes the absolute cross section is needed; for example, to determine the areal concentration of a particular atomic species in the sample, or to quantify the elemental composition of samples. The simplest approach is to measure the absorption coefficient with and without the sample inserted into the beam, as is done in a single beam optical spectrophotometer. Measurement precision can in principle be improved by modulation, i.e. rapidly performing differential measurements by rapidly inserting and removing the sample, for example by using a rotating disk with apertures that alternately contain a sample or a blank. This approach may be impractical for some samples, particularly if they require a special environment such as ultra high vacuum, high pressure, etc. In such cases it is possible to deflect the X-ray beam with a glancing incidence X-ray mirror, or by introducing an X-ray beam splitter.

Measurements of highest accuracy discriminate between the scattered, refracted, and transmitted beams. This can be made possible through the use of crystal analysers following the sample. If the X-ray beam is polarized and statistically non-isotropic, it is important to account for orientation-dependent effects. Magic-angle spinning of the sample can be an effective means of averaging over anisotropies.

Requirements for X-Ray Absorption Spectroscopy

X-ray absorption fine structure experiments require energy resolution on the order of several electron volts or less, to resolve modulations in the spectra. Spectra are intrinsically broadened by the 'core-hole lifetime broadening', which is an effect stemming from the relatively rapid ($<10^{-15}$ s) filling of the core-hole state (initial state vacancy) produced after the X-ray absorption event. Heisenberg's time-energy uncertainty

Figure 1 Absorption and scattering cross sections for (a) platinum, and (b) oxygen.

relation $\Delta E \Delta t \geq \hbar/2\pi$ implies that the rapid decay of the core-hole state broadens the energy spectrum with an energy level width ΔE inversely proportional to the lifetime Δt . The level width increases rapidly with atomic number.

Several stringent criteria must be met before an apparatus can be regarded as a suitable X-ray absorption spectrometer for XAFS. First, the device must have an appropriate energy resolution (several eV or less); tunability (i.e. smooth, reliable scanning over an energy range of more than ~ 1000 eV range above selected absorption edges); and high flux generally $> 10^{10}$ photons s^{-1} . The harmonic content, i.e. contributions from high energy photons at multiples of the selected energy, should be limited to less than 0.1% of the fundamental. Beam intensity variation over a scan should be kept within $\sim 20\%$ depending on the linearity of detectors. **Figure 2** shows the layout of a typical instrument for transmission XAFS experiments.

Sources

The collimated beams, smooth energy spectrum, and high intensity of synchrotron radiation sources offer compelling advantages for XAFS experiments, compared to conventional fixed and rotating anode X-ray generators, although the latter are useful in some situations.

Historically, synchrotron radiation sources were associated with particle accelerators constructed for high energy physics experiments – so-called first generation sources. Electrons or positrons (anti-electrons) are accelerated in a closed orbit through an evacuated pipe at speeds exceedingly close to the speed of light:

$$\frac{v}{c} \sim 1 - \frac{1}{2\gamma^2}$$

where $\gamma = E/mc^2$ and E is the particle energy. These particles are used because particles of low mass radiate energy much more efficiently than those of high mass. Through the use of magnets the path of the particles is bent into a closed path of several hundred to one thousand metres circumference, through which the particles

circulate at frequencies of hundreds of kilohertz to megahertz. Energy lost from the particle beam by synchrotron radiation is replenished through the use of radio-frequency cavities which apply a force to the particles along the direction of motion as they pass by. The particles travel in discrete ‘bunches’, and therefore the radiation produced has a pulsed structure that can be used to advantage for time-resolved experiments. The electrons circulate for many hours; scattering of the electrons from residual gas atoms in the ultra high vacuum environment in the ring, intra-bunch electron–electron interaction, quantum perturbations from spontaneous emission of photons, and other effects cause a slow loss of particles from the beam, which therefore must be periodically refilled. It is technically feasible to periodically replenish the beam and preserve nearly constant current in the ring.

All accelerating charged particles radiate energy, and if it were not for relativistic effects, the radiation produced by a synchrotron would be in the radio-frequency spectrum. The relativistic motion causes the familiar dipole radiation lobes of an accelerating charge (seen in an inertial frame co-moving with the charge) to tilt forward along the direction of motion, in the observer’s reference frame. The radiation pattern from a bend magnet is a horizontal fan of several milliradians angular width in the horizontal direction (in the orbital plane), and it is very well collimated in the vertical direction to an opening angle of order $1/\gamma$, where $\gamma = E/mc^2$, E is the particle beam energy, m is the rest mass of the electron, and c is the speed of light. For all bend magnets the broad spectrum (integrated over vertical opening angle) is described by a universal function

$$g_1(x) \equiv x \int_x^\infty K_{5/3}(t) dt$$

where $K_{5/3}$ is the modified Bessel function of order $5/3$. The spectrum is parameterized by the ‘critical energy’

$$\varepsilon_c = 3 \frac{\hbar c}{4\pi\rho} \gamma^3$$

Figure 2 Schematic of a transmission XAFS experiment.

where ε is the X-ray energy, b is Planck's constant, and ρ is the bend radius [ρ_B (metres) $\sim 3.336 E(\text{GeV})/B(\text{Tesla})$]. The root mean square angular width in the vertical direction can be approximated by $(0.57/\gamma)(\varepsilon_c/\varepsilon)^{0.43}$. **Figure 3** shows the universal spectral curve for bend magnets and planar wigglers (see below).

Second generation sources are constructed specifically to produce bend magnet radiation for experimental use. Third generation sources are optimized for the use of 'insertion devices' – magnetic structures inserted into the particle beam path that modify the trajectory so as to produce synchrotron radiation of the desired energy spectrum, spatial characteristics, and polarization. They are designed for low emittance, which is the product of the spread in momentum and the spread in position of the particle beam (the phase space volume). According to Liouville's theorem, the emittance is conserved as the beam propagates through the dipole, quadrupole, and sextupole magnets used to guide and focus the particles.

Wigglers are arrays of alternating magnetic poles that apply an approximately sinusoidal magnetic field to the particles and cause their trajectory to oscillate. The spectrum and angular radiation pattern is similar to that of an array of bend magnets of alternating curvature, but with the advantages of higher flux owing to multiple magnetic poles, and the critical energy determined by experimental requirements rather than geometrical constraints.

Undulators are similar to wigglers in that they produce an alternating magnetic field that causes the particle trajectory to oscillate in an approximately sinusoidal manner. The tangent direction of the particle trajectory is kept within the intrinsic width of the synchrotron radiation cone, which allows the X-rays emitted at each successive magnetic pole to interfere. This interference

concentrates the energy into narrow energy bands and a narrow angular divergence in both horizontal and vertical directions. The amplitude of oscillation of the particles is characterized by the 'deflection parameter' $K = \gamma \delta_w$, where $\delta_w = \lambda_0/2\pi\rho_0$, λ_0 is the undulator period, and ρ_0 is the bend radius corresponding to the peak magnetic field. For small oscillations, there is a single peak in the spectrum at $2\gamma^2$ times the frequency of oscillation of the particle Ω_w , as measured in the inertial frame of the average particle velocity. Undulators in use for X-ray spectroscopy generally have sufficiently high fields that they have characteristics intermediate between an ideal undulator and wigglers. In this case the particle motion becomes relativistic even in its co-moving reference frame, and harmonics are generated. The X-ray frequency of the fundamental observed at an angle θ_0 is given approximately by

$$\frac{2\gamma^2 \Omega_w}{1 + (K^2/2) + \gamma^2 \theta_0^2}$$

This expression shows that the positions of peaks in the spectrum can be controlled by adjusting the deflection parameter K , by controlling the magnetic field presented to the particle beam. The energy width of undulator peaks is typically of the order of 100 eV, decreasing with the number of poles. The fluxes from even-order harmonics are of significantly lower amplitude, particularly on the undulator axis. **Figure 4** shows the spectrum from an APS type A undulator.

Optics

Monochromators

The desired energy bandwidth of approximately 1 eV is selected by allowing the beam to impinge at a selected angle θ onto a cooled single crystal of silicon,

Figure 3 Synchrotron function $gI(x)$ (solid) and simple approximation (dashes): $f(x) = 1.8 x^{0.3} \exp(-x)$, where $x = \varepsilon/\varepsilon_c$. A more accurate approximation (not shown) is $gI(x) = ax^b \exp(-cx)$ with $a = 1.71857$, $b = 0.281526$, $c = 0.968375$. The spectral photon flux (photons/sec/0.1% bandwidth $(\Delta\varepsilon/\varepsilon)$ /mA beam current/mrad) integrated over the full vertical opening angle is $1.256 \times 10^7 \gamma gI[x]$, with $\gamma = E/mc^2$.

Figure 4 Integrated spectral flux for Advanced Photon Source (APS) undulator. The position of the peaks is adjustable by varying the undulator magnetic gap.

germanium, diamond, or other substance. The crystals reside on a goniometer inside a vacuum chamber or inert atmosphere to minimize ozone production and absorption, and the angle θ can be remotely scanned by a computer. X-rays that meet the Bragg diffraction condition $n\lambda = 2d_{hkl}\sin(\theta)$ are diffracted through an angle 2θ ; the rest are absorbed. In this equation, λ is the X-ray wavelength, which is related to the photon energy $\varepsilon = hc/\lambda$; n is the harmonic number, and the spacing between diffracting atomic planes in the crystal for 'reflection' hkl is $d_{hkl} = a_0/(h^2 + k^2 + l^2)^{1/2}$, where a_0 is the lattice constant (0.357 nm for Si). The crystals used are sufficiently perfect that they are well described by dynamical diffraction theory instead of kinematic theory. Some of the lower index allowed reflections are 111, 220, 311, 400, 331, 422, 333, 511, 440, and 531. Higher index crystals are used to obtain better energy resolution but at the expense of lower integrated reflectivity.

Normally, a parallel second crystal is placed after the first crystal to deflect the beam in a direction parallel to the incident beam direction, so that the X-ray beam angle is maintained constant as the energy is scanned. The first and second crystal faces can be formed from the same piece of silicon by cutting a channel in it, making a so-called channel-cut configuration. Alternatively, separate crystals can be mounted independently of each other. In such a double crystal Bragg monochromator, the beam is displaced by a distance $2H\cos(\theta)$ from the height of the incident beam, where H is the perpendicular separation of the crystals; consequently the beam height varies with energy, typically by less than a millimetre. The beam motion can be tracked by moving the sample and detectors under computer control; alternatively, in appropriately constructed monochromators, H can be adjusted to preserve a fixed beam height. A translation of the second crystal parallel to the first to keep the diffracted beam centred on the second crystal also may be beneficial. A fine adjustment of the relative orientation of first and second crystal is essential; this is accomplished with piezoelectric transducers or highly gear-reduced motors.

The 'rocking curve' – the reflectivity of the crystal versus θ for monochromatic X-rays – is approximately rectangular in shape, with a typical (energy dependent) width of 3–10 arc-seconds (25–50 microradians). The rocking curves have small, but long-range, tails that can degrade the energy resolution, and may distort X-ray absorption spectra in the near-edge region where there may be rapid changes in absorption with energy. The contribution of these tails can be reduced by using a second pair of crystals following the first pair, but at the cost of considerably greater instrumental complexity.

Focusing in the sagittal (usually horizontal) direction can be accomplished by bending the second crystal to an appropriate radius R , given by $2\sin(\theta)/R = (1/u + 1/v)$, where u is the source to optic distance, and v is the optic

to focal point distance. Substantial vertical (meridional) focusing cannot be achieved by bending the second crystal because doing so would cause the incidence angle of the beam on parts of the second crystal to fall outside of the rocking curve.

The high power density produced by undulator beams presents challenges for monochromator designers. The heat deposited in the first crystal creates a 'thermal bump' in the first crystal because the local heating creates thermal expansion in the silicon that degrades the rocking curves, and hence the resolution and throughput. The relevant parameter is the ratio of the thermal conductivity to the thermal expansion coefficient. Several approaches have been devised to deal with this problem. One is to cool the silicon with liquid nitrogen to a temperature around 100 K, which is beneficial because the thermal expansion coefficient is greatly reduced, and the thermal conductivity is increased. Another approach is to cut the crystal so the diffracting planes are at an inclined angle relative to the crystal face, so that the beam is spread over a larger area of the crystal. A third approach is to use diamond crystals instead of silicon, because the thermal conductivity of diamonds greatly exceeds that of silicon. A fourth approach is to use an X-ray mirror or synthetic multilayer as a pre-filter to reduce the power load on the first crystal.

Mirrors

X-ray mirrors are used for rejecting harmonics, focusing, power filtering, displacing the beam, and improving collimation of the beam incident on the first crystal in order to improve energy resolution.

At small angles of incidence (on the order of milliradians), X-rays are totally externally reflected from the surfaces of materials. This effect is the X-ray analogue of ordinary total *internal* reflection that is observed at visible wavelengths when looking from a dense medium into a less dense medium. For most materials, the index of refraction at X-ray energies is a complex number: $\tilde{n} = 1 - \delta - i\beta$, where $\delta = ne^2\lambda^2/2\pi mc^2$ and $\beta = \mu\lambda/4\pi$. The real and imaginary parts describe dispersion and absorption, and are connected through a Kramers–Kronig transform. Here n is the number of dispersive electrons per volume of the material, e and m are the charge and mass of an electron, λ is the wavelength, and μ is the X-ray absorption coefficient. For elemental materials this reduces to $\delta = N(Z/A)\rho e^2\lambda^2/2\pi mc^2$, where N is Avogadro's number, Z is the atomic number, A is the atomic mass, and ρ is the mass density.

Total external reflection occurs at angles $\theta < \theta_c$, where the 'critical angle' $\theta_c = (2\delta)^{1/2}$. θ_c is approximately inversely proportional to the X-ray energy, as shown in **Figure 5**. This allows the experimenter to eliminate

Figure 5 Mirror reflectivity as a function of angle and energy. θ_{ref} is the critical angle at (arbitrary) energy E_{ref} .

harmonics by selecting an angle so that the fundamental is reflected from the mirror, but the harmonics are not.

The reflectivity from a mirror can be expressed as a function of the reduced angle $\phi = \theta/\theta_c$ as

$$R(\phi) = \frac{(\phi - A)^2 + B^2}{(\phi + A)^2 + B^2}$$

where

$$2A^2 = \left[(\phi^2 - 1)^2 + \left(\frac{\beta}{\delta} \right)^2 \right]^{1/2} + (\phi^2 - 1)$$

and

$$2B^2 = \left[(\phi^2 - 1)^2 + \left(\frac{\beta}{\delta} \right)^2 \right]^{1/2} - (\phi^2 - 1)$$

For a given angle, materials or coatings of high atomic number have larger critical energies, which allow them to reflect X-rays at higher energies. The disadvantages of using high Z coatings are lower reflectivity and a less sharp cutoff of reflectivity against energy. This is a consequence of absorption in the material, the effect of which is shown in **Figure 6**. The product of energy and θ_c is an intrinsic property of the material coating: representative measured values (in KeV mrad, $\pm 2\%$) are Si (31), Ni (59), Pd (62), Rh (67), Pt (82), Au (80).

X-ray mirrors are fabricated from polished glass (float glass, ultra low thermal expansion titanium silicate), silicon, silicon carbide, appropriate ceramics, or metal substrates. Typically they are tens to hundreds of centimetres in length in order to accept the vertical divergence of the beam. Surface roughness degrades the reflectivity, and accordingly the best mirrors are highly polished to as little as ~ 0.2 nm root mean square roughness. With present technology, ångström-level roughness and microradian rms slope errors are

Reflectivity for $\beta/\delta = .001, .01, .1$

Figure 6 Effect of X-ray absorption from mirror coatings on reflectivity. See text for explanation.

achievable over mirror lengths of more than 1 m. Meridional focusing in the vertical direction can be accomplished by bending a short mirror to an appropriate radius, given by $2/(R \theta) = (1/u + 1/v)$, where u is the source to optic distance, and v is the optic to focal point distance. Longer mirrors can be used provided the local radius of curvature at each point on the mirror satisfies this focusing equation.

Detectors

Ionization chambers are the most commonly used detectors for X-ray absorption spectroscopy. They have the virtue of being partially transparent so that the incident beam intensity can be monitored. Typically they consist of a pair of parallel conducting plates several cm in each dimension and separation approximately 1 cm, inside a gas-tight housing in which is placed an appropriate gas (e.g. helium, nitrogen, argon, krypton). The gas can be flowed through the chamber, or sealed inside under positive, negative or ambient pressure. A constant potential of hundreds to thousands of volts is applied between the plates using a high voltage power supply or battery, and the small current flowing between the plates

through the gas between them is measured. The X-ray beam is allowed to pass between the plates, which ionizes the gas molecules, rendering the 'fill-gas' partially conductive. The current (microamperes to nanoamperes) is proportional to the photon flux, given approximately as $N(E/E_{cc})(1 - \exp(-\mu_{fg}(E)l))$, where N is the number of photons per second of energy E , E_{cc} is the mean energy required to produce a charge carrier in the gas (typically around 32 eV), μ_{fg} is the absorption coefficient of the fill gas (or mixture), and l is the active length of the plates. The current is amplified with a transconductance (current to voltage) amplifier, and read by a computer with an analogue to digital converter; or it is converted to pulses with a voltage to frequency (V/F) converter and counted by a scaler.

Absorption within an ionization chamber is controllable by selection of fill-gas composition and pressure. For reliable absorption measurements, ionization chambers must be carefully constructed and operated at sufficiently high bias voltage that they are linear, i.e. the output current is linearly related to the absorbed photon flux. Under these conditions the chamber is said to be in the 'plateau region' of the flux versus bias voltage curve.

PIN diodes (positive-intrinsic-negative) are semiconductor devices that act essentially as solid state ion chambers. X-rays absorbed by the diodes create electron hole pairs that act as charge carriers. The electric field acting to separate them in the intrinsic (undoped) region is produced by the adjacent positively and negatively doped regions. The charge collected is amplified in the same manner as in an ionization chamber. A bias voltage can also be applied to alter the operational characteristics. PIN diodes are capable of excellent linearity but the X-ray thickness is not as easily experimentally controllable as it is for ionization chambers.

Ionization chambers with X-ray transparent plates made of aluminized plastic or thin metallic mesh are used for detection of fluorescence radiation. Detection of the fluorescence from dilute species requires a means of rejecting elastically scattered background from the sample. X-ray filters and slits used with ionization chambers are a standard method of rejecting background. Alternatively, arrays of solid state detector elements with appropriate electronics can provide useful energy resolution and adequate count rates for many purposes. Eliminating the scattered radiation with synthetic multilayer or crystal analysers is a promising approach for third generation synchrotron radiation sources.

The methods described in this article with reference to proteins are also used in studying other biological macromolecules such as nucleic acids, viruses, and their complexes.

Although invaluable information about the structure and properties of proteins has come from a variety of spectroscopic techniques and electron microscopy, most of the available 3-D information has been obtained by X-ray crystallography. Why X-rays? X-rays happen to have wavelengths of the same order of magnitude as the distances between atoms in molecules, so that they can resolve information about atomic arrangements. Why crystals? Because single atoms or molecules only react very weakly with the X-rays whereas crystals are ordered arrangements of atoms or molecules, which 'sing in unison' when they scatter X-rays.

Although it is perhaps surprising that irregularly shaped molecules, as most proteins are, can form regular crystals, they can do so because the gaps between molecules are filled by the 'mother liquor' from which the crystals are grown, commonly dilute solutions of salts such as ammonium chloride. It is essential to prevent the crystals from drying out; traditionally achieved by enclosing the crystal in a thin-walled capillary, commonly nowadays by freezing the crystal during its exposure to X-rays.

The light and electron microscopes are able to form direct images of objects because lens systems are available to bring light rays and electron beams to a focus. Unfortunately, there are no substances that can bend X-ray beams in a similar way, and the process of deriving images of molecules using X-rays is more complex. X-rays, like light rays, are forms of electromagnetic radiation that have wavelike properties: (1) wavelength, dependent on the source of the rays; (2) amplitude; (3) phase, the relative position of the peaks and troughs of the waves. If, when two waves come together, their peaks and troughs coincide, they are said to be 'in phase,' and they will reinforce each other; if the peaks of one ray coincide with the troughs of the other, they are 'out of phase' and will tend to cancel each other, completely so if they have similar amplitude; if their

phases differ by an amount other than a whole or half wavelength, the result will be partway between complete reinforcement and complete cancellation (**Figure 1**).

In a light microscope, image formation comprises two stages: first, the light is scattered by each feature in the object, the scattered rays having different amplitudes and different phases, the latter depending on the paths taken by the rays; second, the scattered rays are recombined and brought to a focus by the lens system. The lens system preserves the phases of the light rays, so that when they arrive in the focal plane, they retain the same relative phases they had when they emerged from the object, with the result that the final image looks just like the object. But in the case of X-rays, no lenses are available and all that can be done is to record the pattern of rays scattered by the crystals; whichever method is used to record this pattern, the intensity of the rays (which is the square of their amplitudes) can be measured but not their phases. This is known as the 'phase problem' of X-ray crystallography – fortunately, it may be overcome in various ways, described in the following text.

Forms of Molecular Crystals

In the simplest possible arrangement, all the molecules in a crystal would be facing exactly the same way. They would form rows in three directions (left/right, up/down, and back/front), but the three directions would not normally be at right angles to each other, as the molecules are not rectangular blocks. Some crystals of proteins have this

Figure 1 Summation of waves of similar wavelength but different amplitude and phase. The downward-pointing arrows show the positions of the peaks of the waves.

simple arrangement, but more commonly, awkwardly shaped molecules can be packed more efficiently if they do not all face the same way – for instance, molecules can face alternate ways along one direction in the crystal (Figure 2).

There is an important difference between simple chemical compounds and natural proteins: simple compounds can often adopt mirror-image forms, whereas natural proteins, nucleic acids and carbohydrates only have ‘one hand’ – proteins are made of L-amino acids, for example; therefore crystals of proteins cannot have any ‘mirror-symmetry,’ unlike crystals of some small molecules, metals or salts or the 2-D patterns of wallpaper or fabrics. Even so, it turns out that there are over 60 different ways in which asymmetrical molecules can be packed together to fill space efficiently. Nevertheless, in every case a crystal is built up from a fundamental repeating pattern, the *unit cell*, which comprises a single molecule or a small number of molecules related to each other by rotations or translations within the cell. The most common crystal symmetries are ‘monoclinic,’ in which two of the angles between cell edges are 90° , but the third is $>90^\circ$, and ‘orthorhombic’ in which all three angles are 90° . Crystallographers use complicated-looking expressions such as $P2_12_12_1$ to describe crystal symmetry (in this case, an orthorhombic cell containing four molecules that are alternately ‘right way up’ and ‘upside down’ when viewed along each of the three axes in turn). An alternative way of describing such an alternating up and down relation is to say that the molecules lie on twofold screw axes, meaning that molecules are rotated by $360/2$ degrees as they are translated $1/2$ of the distance along the relevant cell edge.

Figure 2 (a) The ‘molecules’ are all facing the same way. None of the cell axes are at 90° to each other. (b) An alternative mode of packing, with a larger unit cell that contains two ‘molecules’; they are related by twofold rotation axes that are perpendicular to the plane; now, two of the cell angles are 90° , but, the unit cell edges in the plane are not at 90° to each other.

Other types of crystal symmetry allow for n -fold rotation axes, where related molecules are rotated through $360/n$ degrees, and n -fold screw axes in which in addition to being rotated, they are translated $1/n$ of the distance along the cell edge; n may take the values 2, 3, 4, or 6. The notation describing the full symmetry of the crystal is known as its *space group*. These apparently esoteric aspects of crystal symmetry have been discussed here because there have been a number of incorrect published structures arising from the failure of the authors to analyze the crystal symmetry correctly. In particular, measurement of one or more of the unit cell angles as 90° is normally diagnostic of the presence of even-fold rotation axes in the cell contents; very occasionally, incorrect symmetry has been deduced when a cell angle has been thought to be 90° despite having a small deviation from that exact angle.

Interaction between X-rays and Crystals

When X-rays collide with the electron clouds around atoms, the electrons are stimulated to emit radiation of the same wavelength as that of the incident rays and normally, with exceptions described in the following text, exactly in phase with the incident rays. The scattered rays produced by all the atoms in the crystal add together in a way first described by WL Bragg. Let us first reduce the crystal to the regular 3-D array formed by placing a single atom at the corner of each unit cell. Sets of equidistant planes passing through the atoms in very many directions can then be drawn (Figure 3). Consider a parallel beam of rays

Figure 3 The thin black lines show a crystal lattice. Sets of planes can be drawn through a crystal in very many different ways. The blue lines represent one such set. WL Bragg's construction showed that X-rays (red lines) incident on one of these planes are in effect reflected if the rays scattered by different atoms on the plane are to be in step with one another. If rays reflected from the neighboring plane are also to be in step, the extra distance traveled ($2d \sin \theta$) must be a whole number of wavelengths ($n\lambda$).

incident on one plane of atoms. The X-rays scattered by all the atoms in that plane would tend to cancel each other out except in one direction, in which the plane of atoms was acting like a mirror, with the angle of the emergent beam to the plane being equal to the angle of incidence of the beam on that plane. But the incident beam would also penetrate to the atoms in the next layer of the crystal, producing another scattered beam. This second beam would have traveled further than the first and would therefore be out of phase and tend to interfere with the first unless the extra distance travelled was a whole number of wavelengths. Scattering is therefore seen only at certain angles given by the Bragg equation $n\lambda = 2d \sin\theta$, where n is an integer, λ is the X-ray wavelength, d is the distance between the planes of atoms, and θ is the angle of incidence and reflection. Each further parallel plane of atoms in the crystal will add to the amplitude of the scattered radiation.

The result is that, if the X-ray beam is monochromatic (i.e., a single wavelength) the crystal has to be rotated around and a scattered beam will be formed whenever a set of planes makes the appropriate angle to the incident beam. It is usual to refer to 'X-ray reflections' because of the similarity of this behavior to reflection from a mirror.

This simple explanation is complicated by two factors. First, in a real molecular crystal, there is not just a single atom per unit cell but a large number. It is therefore necessary to add together the contributions from all the individual atoms within each molecule (and the solvent molecules of the mother liquor). In general, these will all be out of phase with each other, and to a different extent depending on the direction of the rays through the crystal (Figure 4). Scattered rays will only appear in the directions given by Bragg's law, but they will vary in

Figure 4 Rays scattered by different atoms within the molecule will almost certainly be out of step to some extent.

strength because of the molecular structure. The second complicating factor is relatively minor; if, as is most common, there are more than one molecule in each unit cell, there will be interference between the rays scattered by one molecule and those by its symmetry-related partner(s). If, for example, the crystal possesses a twofold screw axis, for some directions of the crystal planes there will be a set of molecules exactly halfway between another set, and this will result in complete cancellation of the X-rays that would have been reflected from those planes, leading to a 'systematic absence' of spots in parts of the pattern – this result is useful in identifying the space group of the crystal.

The X-ray diffraction pattern shown in Figure 5 was obtained on a special type of X-ray 'camera' in which the crystal is moved around (together with a photographic film), in a way that causes the reflections to be regularly spaced on the film.

The complete diffraction pattern from a crystal can be considered as a 3-D array of spots, of which a film such as this one is a cross-section. This film shows (1) the array of spots, regularly spaced in each direction, the distance between them allowing the unit cell dimensions to be worked out and (2) the very great variation between the intensities of the different spots – this variation is directly related to the distribution of electrons within the unit cell. The spots are given indices h,k,l corresponding to the three axes of the pattern.

Figure 5 Photographic film of the X-ray pattern given by a protein crystal. The central white spot is from a lead beamstop that prevents the direct X-ray beam from hitting the film. A careful look at the central vertical and horizontal rows shows that alternate spots are missing, because the four molecules in the unit cell are related by twofold screw axes.

Measurement of X-ray Diffraction Patterns

The generation of X-rays was pioneered by Röntgen who applied a high voltage between an electron-emitting cathode and an anode, which expelled X-rays. A similar principle was used for many years, normally with a copper anode that gave monochromatic X-rays of a convenient wavelength. The continuous bombardment of the anode by the electrons heats it up and, to increase the intensity of the X-ray beam, 'rotating-anode' generators were developed in which copper forms the surface of a water-cooled cylinder rotated at high speed. An alternative approach arose from the realization that the radiation flung off from electron synchrotrons, regarded as a nuisance by those interested in particle accelerators, could be a useful source of X-rays for structural studies. An essential difference from conventional sources is that a continuous range of X-ray wavelengths is produced, so that it is possible to obtain diffraction patterns at different wavelengths. There is a downside to the use of synchrotron radiation, namely, that it is only available at a few places around the world, so that most users have to travel away from their home laboratories to collect data at them.

For many years, the preferred method of measuring the diffraction patterns from crystals of proteins was photographic film; this was facilitated by M Buerger's design of the precession camera, the geometry of which resulted in the spots occurring in straight lines (see **Figure 5**), where they could be scanned by semiautomatic densitometers. These were succeeded by diffractometers with which the reflections could be measured with electronic 'proportional counters' with computer-controlled movement of counter and crystal, and data fed directly into a computer. These were relatively slow as only one (or later, up to five) reflections could be measured at a time, making exposure times much longer than for the precession films with their facility of recording many reflections in parallel. Nowadays, such instruments have largely been superseded by electronic 'area detectors' of various types enabling many reflections to be measured in parallel and the data input to the computer.

As explained earlier, crystals of proteins necessarily contain fluid filling the gaps between them, and the traditional method for data collection has been to mount them in a sealed thin-walled capillary, containing also some 'mother liquor' to prevent them from drying out. This method has the disadvantage of causing the X-ray beams to be absorbed by the capillary walls and liquor, with the resultant need to correct for the absorption. The more recent method has been to mount the crystal on a glass fiber, to immerse it rapidly in liquid nitrogen, and to maintain it in a cooling jet of dry nitrogen during data collection with a temperature below 190 °K, where the

interstitial water adopts a glassy state. This technique removes the need for an absorption correction and reduces the radiation damage that occurs as a result of the creation of free radicals by the X-radiation.

Fourier Analysis

The mathematician Joseph Fourier showed that any periodic function could be represented by the sum of sinusoidal waves. The most familiar application is the harmonic analysis of the sound from a musical instrument, which can be built up by addition of the fundamental vibration and higher harmonics of it. The electron density of a crystal, with its regularly repeating pattern of unit cells, is a 3-D periodic function and it turns out that the amplitudes of the diffracted rays from a crystal are proportional to the amplitudes of the Fourier components of the 3-D electron density function. By measuring the amplitudes of all the X-ray reflections, it should therefore be possible to calculate their 'Fourier transform,' namely, the actual electron density distribution in the crystal. There is, however, a problem in doing this calculation: namely, the 'phase problem' referred to earlier, which means that, although the amplitudes of the components are known, they cannot be added up correctly without knowledge of their relative phases.

Solving the Phase Problem

Isomorphous Replacement

The amplitude of the X-ray beam scattered by an atom is proportional to the number of its electrons, that is, the atomic number of the atom. Apart from a few sulfur atoms, proteins contain only atoms of relatively low atomic number (C, N, and O plus of course H). Max Perutz realized that if one or two atoms of high atomic number such as Hg could be introduced into a protein molecule, their electron density would stand out in the sea of the protein atoms. Fortunately, each subunit of the hemoglobin on which he was working has a single sulfhydryl group to which a mercurial compound can be covalently bound; moreover, the complex can be crystallized and turns out to have cell dimensions unchanged from those of the 'native' hemoglobin; this added group apparently just displaces solvent molecules without severely perturbing the protein molecule. When the diffraction pattern from the derivative was compared to that of the native protein, many of the spots showed marked changes in intensity – could these changes help to determine the phases of the X-ray reflections (**Figure 6**)?

The first problem was to locate the Hg atoms. This was done by calculating a Patterson map. Lindo Patterson had shown that a Fourier transform calculated using the intensities of the X-ray beams and taking all of their phases

Figure 6 In a vector diagram, the lengths of the lines represent the amplitudes and the angles the phases of the X-rays. This diagram shows that the contribution to the scattered X-ray from the added heavy atom F_H is not normally aligned with the protein contribution F_P ; the resulting amplitude in the protein/heavy atom complex F_{PH} is given by completing the triangle.

equal to zero yielded a map containing peaks showing not the position of the atoms, but the lengths and directions of vectors between pairs of atoms. The vector map is more complicated than the actual structure; for instance, if there are three atoms in a structure, there are six interatomic vectors – the vector from atom A to atom B is accompanied by the vector from atom B to atom A in the opposite direction. Perutz reasoned that with very few atoms (only one Hg per hemoglobin subunit), the positions of the Hg atoms in hemoglobin could be found by calculating a Patterson map using the differences in intensity between each pair of reflections from the native and derivative crystals. Knowing the positions of the Hg atoms, it would then be possible to calculate the contribution they would make to each reflection, both in amplitude and in phase. At this stage, the following were known: the amplitude of the wave for the native protein; the amplitude of the wave from the Hg derivative; and both amplitude and phase of the Hg contribution. A ‘phase triangle’ can then be drawn, as shown in solid lines in **Figure 7**, which indicates the phase of the native protein contribution. Unfortunately, the triangle in broken lines also fits the data, so there is an ambiguity. This can be surmounted if a second heavy atom derivative can be prepared with the heavy atom in a different place; again, there are two possible solutions but, with luck, only one of them fits both sets of data (**Figure 8**).

Because there are significant errors of measurement in all of the X-ray intensities and possible errors in working out the positions of the heavy atoms, it is normal to try to obtain four or five different heavy atom derivatives. The method is therefore referred to as multiple isomorphous replacement (MIR).

Proteins do not always contain several specific ‘hooks’ like the sulfhydryl groups in hemoglobin, but it is often the case that protein crystals will contain local environments into which various chemical groups will fit; although there may be advantages in obtaining a covalent derivative of the protein before crystallization is attempted, it is very common to crystallize the protein first and then to add appropriate compounds to the vessel in which the crystals have formed

Figure 7 Construction to find the protein phase for a single isomorphous derivative. Circles drawn with radius F_P and F_{PH} , respectively, from the ends of the heavy atom vector F_H intersect to reproduce the correct triangle, but also a second, incorrect one.

Figure 8 Construction to find the protein phase for two isomorphous derivatives. The double lines are the vectors for the second derivative. The two correct solutions coincide, whereas the false ones differ.

in the hope that the heavy atom containing compound will diffuse into the crystal and find a specific site for which it has an affinity. Salts of mercury, uranium, and platinum are commonly used; in the case of enzymes, for example, they may be compounds related to the enzyme’s substrate, although this may be hazardous as the binding of substrate molecules often leads to a conformational change of the protein structure rendering it nonisomorphous with the native state.

Anomalous Scattering

The diffraction pattern of a crystal is normally centrosymmetrical, that is, reflections with indices h, k, l and $-h, -k, -l$ (usually written $\bar{h}, \bar{k}, \bar{l}$) are identical in intensity; these can be thought of as being rays reflected, respectively, from the front and the back surface of a set of planes, the only difference being that the material between each pair of planes is encountered in the opposite order. However, if the incident X-ray photons have an energy close to that required to bring electrons of an atom to an excited state, that is, they are close to an absorption edge for that atom, the electrons will not vibrate in step with the incident X-ray beam, causing the radiated energy to have a different phase from the incident ray. This is known as anomalous scattering. It happens that the normal X-rays from an X-ray tube with a copper anode are close to the absorption edges of elements such as iron, palladium, mercury, and uranium. Consequently, with isomorphous derivatives of proteins containing such heavy atoms, the changes of phase of rays scattered by them lead to intensity differences between the h, k, l and $\bar{h}, \bar{k}, \bar{l}$ reflections. Although these differences are much smaller than the normal differences due to the heavy atoms, the errors associated with the differences are also much less as they are obtained from two reflections from the same crystal measured at almost the same time, whereas the isomorphous replacement differences are obtained from measurements from two different crystals. The anomalous scattering differences may be used with mathematical constructions analogous to those in the isomorphous replacement method, and by a combination of the two effects, unique phase determination may be possible using single isomorphous replacement with anomalous scattering (SIRAS). Multiple isomorphous replacement with anomalous scattering (MIRAS) is the combination achieved with multiple derivatives.

A powerful advance has come through the use of synchrotron radiation, for which it is possible to select the wavelength of the X-rays and therefore to 'tune' it with reference to the absorption edge of selected atoms in the protein. It is possible to optimize the anomalous effects by measuring data on either side of an absorption edge.

Even more powerful is the approach that can be used with synthetic proteins, for which it has been found that selenomethionine can be incorporated without distortion in place of natural methionine. The X-ray wavelengths can then be chosen with reference to the selenium absorption edge. This is becoming a very widely used method, effectively combining isomorphous replacement and anomalous differences using a single crystal.

Molecular Replacement

In the simplest case, for example, two proteins may differ by the addition of a ligand to one of them, or by

substitution of one or two amino acids. In each of these examples, it is a reasonable assumption that the protein structures will be essentially identical and it should be possible to obtain the structure of the modified protein by using the intensities of the X-ray pattern from it together with the phases from the original protein. It has been shown that the differences will usually show up with half weight.

In less simple cases, there may be (1) two different crystal forms of the same protein grown from different solvents; (2) crystals of the protein from different organisms, or (3) crystals of related proteins from the same or different organisms. There are decreasingly strong expectations in the three cases that the proteins should have similar structures. Even though the crystal unit cells and symmetries might be quite different, there is the intuitive expectation that the diffraction patterns must contain related features. The most successful method to search for possible relationships is based on the Patterson method; when similar molecules are packed in different ways in the crystals being compared, their Patterson maps should contain some similar features, representing vectors between atoms within each of the molecules, superimposed on a different set of features arising from vectors between atoms in neighboring molecules in the two crystal lattices. Computational methods have been developed to search for the similarities, to use them to find the position and orientation of the yet unknown molecule in its unit cell and thence to use the known structure to deduce the required phase information for structure solution. In many cases, this method has been very successful, even when the expected similarities only involve parts of the molecule. Unfortunately, the method sometimes fails despite strong evidence for a high degree of homology.

Calculation and Interpretation of Electron Density Maps

Having measured the amplitudes and derived the phases of the X-ray reflections from a crystal, it is possible to carry out a 'Fourier synthesis' for the crystal, the values of which give the electron density at all points within the crystal unit cell, which can then be interpreted by the arrangement of the atoms whose electron clouds scatter the X-rays (**Figure 9**). The formula used is as follows:

$$\rho(x, y, z) = \frac{1}{V} \sum_h \sum_k \sum_l F(h, k, l) \cos \{2\pi(bx + ky + lz) - \phi(h, k, l)\}$$

where

$\rho(x, y, z)$ = electron density at position (x, y, z) in the cell

$F(h, k, l)$ = amplitude of ray from crystal planes (h, k, l)

$\phi(h, k, l)$ = phase of ray from crystal planes (h, k, l)

V = volume of unit cell of crystal.

Figure 9 Contour map of part of the electron density for the protein lysozyme at 2.0 Å resolution. The photograph is from a stack of 10 transparent sheets representing about one-sixth of the height of the molecule. The symbols near top left and bottom right indicate the position of the crystal twofold and fourfold axes. The long arrow lies along the axis of an α -helical region of the chain – the ‘promontories’ of density pointing to the left and downward are due to main-chain carbonyl groups. The very dense round blob marked ‘S’ is one of the atoms of a disulfide bridge, in which the two S atoms lie one above the other in this view. All four corners of the map are relatively featureless because they are the solvent regions surrounding the molecule.

The formula looks complicated, but it is actually quite straightforward to calculate.

The amount of detail in the image depends on the range of data that has been collected (and included in the summations). If only the central region of the complete data set has been recorded, that is, only at fairly small θ angles (small values of h, k, l), then only gross features of the molecular structure will be recognizable. There is always a degree of disorder due to thermal motion and slight differences between individual molecules in even the best protein crystals, so that the diffraction pattern fades out at higher angles and only in a few cases is it possible to see individual atoms. Fortunately, however, the geometries of the components from which proteins and other biomolecules are built up are known, so the molecular conformation can be deduced even if individual atoms cannot be seen.

The earliest protein electron density maps were plotted as contour maps on transparent sheets, and the models built with metal components to match the shape of the contours. Nowadays, computer graphics techniques allow the contours to be drawn and the model to be built on a computer screen. Much is known about the bond lengths and interbond angles of the amino acids, but

none of these parameters is absolutely rigid, and experience is required to assess how much flexibility should be allowed in interpreting the way in which the chains have to be folded to fit into the electron density. Residual errors in the maps and flexibility in some parts of the molecule, together with complex geometrical arrangements in some regions, for example, where two parts of a protein chain are linked by a disulfide bridge, present further difficulties.

Refinement and Evaluation of the Model

Once a set of coordinates has been found for the majority of atoms in the molecule, it is possible to calculate the amplitudes and phases for the X-ray reflections that the model of the molecule would give and compare them to the experimental values. The atomic positions are then subjected to a process of refinement, normally using a least squares method, to reduce the discrepancies between the observed and the calculated X-ray data. However, unless the highest resolution data are available, the number of parameters to be adjusted (the three coordinates for each atom and a ‘temperature factor’ to allow for the thermal movement of the atoms) exceeds the available number of observations. This problem is surmounted by ensuring that the atoms do not move individually, but that they are restrained so as to maintain bond lengths and angles within acceptable limits. Successive rounds of positional adjustment alternating with recalculation of the map (which should improve at each stage) and inspection of the map for any adjustments that now appear to be needed are carried out until convergence has been achieved.

Further methods of improving the model include: (1) ‘solvent flattening’; apart from a few solvent molecules close to the surface of the biomolecule, there should be little detail in the gaps between molecules – in some cases, it may help to cut out all density in such regions and recalculate the map using phases derived from the remaining features; (2) ‘omit maps’; if there is ambiguity in the positioning of some parts of the molecule, notably side chains, it is normal to recalculate maps using phases derived from models from which the doubtful atoms have been omitted – this is certainly better than putting them in the wrong places; (3) ‘molecular averaging’ may be used in cases where the unit cell contains two or more copies of the molecule that are not related by the crystal symmetry, but where there is good reason to expect them to have similar conformations.

It is then normal to assess the geometry of the model, invariably including in the case of proteins the calculation of a ‘Ramachandran plot’ to show that the conformational angles along the polypeptide chain fall sufficiently well into the energetically allowed regions. It is standard practice in

the profession for structural data to be deposited in the international Protein Data Bank (see www.wwpdb.org), where there is rigorous checking of the data. Nevertheless, incorrect interpretations of unclear regions of electron density maps occur occasionally, and the errors may not be noticed if the vast majority of the model is correct. Despite the name 'Protein Data Bank,' inherited from its original establishment, the bank holds structural details of nucleic acids, viruses, and other biomolecular complexes.

Symbols

c^i	coefficient of Ψ^i
E_0^{nl}	total energy of neutral atom A with a vacancy at the nl level
E_{init}	initial energy of system
E_{fin}	final energy of system
E_r	relaxation energy
$h\nu$	energy of emission quantum
I	intensity of X-ray emission lines
N_{Snp}	np level population of sulfur atom
q_A	effective charge on atom A
ε_{np}	one-electron energy of np level
Φ_{S1s}	wavefunction of the sulfur $1s$ orbital
Ψ^i	wavefunction of the i th MO

MO Structure Investigation

Any variations in the composition, structure, stereochemistry or coordination character of a molecule change its chemical properties and MO (molecular orbital) structure. MO changes are clearly observed by the fine structure of XFS (X-ray fluorescence spectroscopy). This

makes it possible to relate some features of the chemical behaviour of compounds to their electronic structure and opens a way to various ‘chemical property–electronic structure parameter’ correlations which are frequently of help for explaining and predicting the chemical properties of compounds.

The transitions from valence atomic levels to vacancies in inner shells form X-ray valence emission lines, reflecting the structure of the valence levels or zones. Electron transitions between different inner levels form inner X-ray emission lines. The study of the fine structure of different valence emission lines of all the atoms in a compound allows detailed investigation of the structure of valence levels or zones. Research into the shifts of inner X-ray emission lines allows one to investigate effective charges on the corresponding atoms.

For example, consider the X-ray emission spectra of sulfur. The initial state of a sulfur atom for X-ray emission is that with a vacancy in the K or $L_{2,3}$ level. This vacancy is rapidly filled (within $10^{-16} - 10^{-14}$ s) as a result of transitions obeying the dipole selection rules, i.e. $2p \rightarrow 1s$ ($K\alpha$ lines), $3p \rightarrow 1s$ ($K\beta$ lines) or $3s \rightarrow 2p$, $3d \rightarrow 2p$ ($L_{2,3}$ lines) transitions. The energy released in this case is emitted from the atom as either an Auger electron or an X-ray quantum (Figure 1).

Figure 1 Scheme showing the change of one-electron energies of $1s$, $2p$ levels and the energy of the $A K\alpha$ line in the ions A^+ and A^- with respect to the neutral atom A^0 .

Whereas SK α are inner lines, SK β and SL_{2,3} are valence lines. The energies of atomic np $\rightarrow$ 1s transitions can be represented by the equations

$$h\nu = E_{\text{fin}} - E_{\text{init}} = E^{-\text{np}} - E^{-1s} \quad [1]$$

$$\begin{aligned} \Delta h\nu &= \Delta E^{-\text{np}} - \Delta E^{-1s} \\ &= \Delta E^{-\text{np}} \approx \Delta(E^0 - \varepsilon_{\text{np}}) = -\Delta\varepsilon_{\text{np}} \end{aligned} \quad [2]$$

where $h\nu$ is the energy of the emission quantum, E_{fin} is the final energy of the system, E_{init} is the initial energy of the system, $E^{-\text{nl}}$ is the energy of the system with an nl electron removed and ε_{np} is the one-electron energy of the np level.

Thus, in a one-electron approximation the distance between individual maxima in a spectral series is equal to the difference in one-electron energies of the corresponding atomic levels. In molecules the 3s, 3p and 3d electrons of the sulfur atom are involved in chemical bonding to form an MO system. In this case, the SK β spectrum (S3p $\rightarrow$ S1s interatomic transitions), for example, corresponds to MO_{*i*} $\rightarrow$ S1s transitions, and the distances between spectral maxima correspond to energy differences of the appropriate occupied molecular levels:

$$\Delta E_{ij}(\text{SK}\beta) = \varepsilon(\text{MO}_j) - \varepsilon(\text{MO}_i) \quad [3]$$

The intensity of X-ray emission lines is determined by the relation (for the SK series as an example):

$$I(\text{Snp} \rightarrow \text{S1s}) \sim N_{\text{Snp}} E_1^3 |\langle \Phi_{\text{Snp}} | r | \Phi_{\text{S1s}} \rangle|^2 \quad [4]$$

where N_{Snp} is the np level population of the sulfur atom, E_1 is the energy of Snp $\rightarrow$ S1s transitions, Φ_{Snp} is the wavefunction of sulfur np orbitals and Φ_{S1s} is the wavefunction of the sulfur 1s orbital.

For molecules this expression is transformed to the equation

$$I(\text{MO}_i \rightarrow \text{S1s}) \sim N_i E_1^3 |\langle \Psi^i | r | \Phi_{\text{S1s}} \rangle|^2 \quad [5]$$

where Ψ^i is the wavefunction of the *i*th MO.

In the generally accepted MO LCAO model the wavefunction of any *i*th MO can be represented as an AO sum:

$$\Psi^i = \sum_j c_j^i \Phi_j \quad [6]$$

where Φ_j is the wavefunction of the *j*th AO and c_j^i are the coefficients.

Then, with account taken of the dipole selection rules, eqn [5] is transformed into

$$\begin{aligned} I(\text{MO}_i \rightarrow \text{S1s}) &\sim N_i E_1^3 \left| \left\langle \sum_j c_j^i \Phi_j | r | \Phi_{\text{S1s}} \right\rangle \right|^2 \\ &= N_i E_1^3 (c^i)^2 |\langle \Phi_{\text{S3p}} | r | \Phi_{\text{S1s}} \rangle|^2 \end{aligned} \quad [7]$$

where c^i is the coefficient of Ψ^i at the wavefunction of S3p AO (Φ_{S3p}). Thus, the ratio of partial intensities in the SK β spectrum of a molecule is equal to that of the squares of the coefficients of the S3p wavefunction in the expansion of the corresponding MOs in terms of AOs:

$$I_i : I_j : I_k = (c^i)^2 : (c^j)^2 : (c^k)^2 \quad [8]$$

The above is also true for other X-ray emission series. Important features of X-ray emission spectra are the comparative ease of interpretation and the possibility of investigating the electronic structure from the 'viewpoint' of any atom of the molecule investigated.

Example: Electronic Structure of the Sulfate Ion

Information concerning the electronic structure of molecules provided by XFS can be well illustrated with the sulfate ion as an example. The wavefunction of any *i*th valent MO of the sulfate ion can be described by the equation

$$\begin{aligned} \Psi^i &= c_1^i \Phi_{\text{S3s}} + c_2^i \Phi_{\text{S3p}} + c_3^i \Phi_{\text{S3d}} + c_4^i \Phi_{\text{O2s}} \\ &+ c_5^i \Phi_{\text{O2p}} \end{aligned} \quad [9]$$

Figure 2 Full set of X-ray fluorescence spectra of the sulfate ion on an energy scale corresponding to the ionization potentials of valence electrons.

All possible X-ray fluorescence spectra of the sulfate ion are presented in **Figure 2** whereas **Figure 3** shows an MO diagram constructed from a full set of these spectra. 'Adjustment' to the scale of the ionization potentials [IP] of valence electrons is effected by subtracting the X-ray transition energies from the IPs of the corresponding inner levels (S1s, S2p, O1s) determined by the use of data from X-ray photoelectron spectroscopy:

$$E_i(\text{SK}\beta) = \text{IP}(\text{S1s}) - \text{IP}(\text{MO}_i) \quad [10]$$

$$E_j(\text{SL}_{2,3}) = \text{IP}(\text{S2p}) - \text{IP}(\text{MO}_j) \quad [11]$$

$$E_k(\text{OK}\alpha) = \text{IP}(\text{O1s}) - \text{IP}(\text{MO}_k) \quad [12]$$

From these, the following equations are derived

$$\begin{aligned} \text{IP}(\text{MO}_i) &= \text{IP}(\text{S1s}) - E_i(\text{SK}\beta) \\ &= \text{IP}(\text{S2p}) + E(\text{SK}\alpha) - E_i(\text{SK}\beta) \end{aligned} \quad [13]$$

$$\text{IP}(\text{MO}_j) = \text{IP}(\text{S2p}) - E_j(\text{SL}_{2,3}) \quad [14]$$

$$\text{IP}(\text{MO}_k) = \text{IP}(\text{O1s}) - E_k(\text{OK}\alpha) \quad [15]$$

All MOs with $c_5 \neq 0$ are displayed in the O K α spectrum (O2p $\rightarrow$ O1s transitions), those with $c_2 \neq 0$ in the

SK β spectrum (S3p $\rightarrow$ S1s transitions) and those with $c_1 \neq 0$ and $c_3 \neq 0$ in the SL_{2,3} spectrum (S3s $\rightarrow$ S2p and S3d $\rightarrow$ S2p transitions). From the transitions shown in **Figure 3** it follows that the highest occupied MO 1t₁ (maximum A in the OK α spectrum) consists of only O2p electrons; next, the 3t₂ and 1e levels (maxima B, C and W) significantly correspond to the π bond S3d – O2p; the 2t₂ level then follows (maxima D and F), which corresponds to the strong S3p – O2p σ bond. The 2a₁ level (maxima E and V), consisting of the S3s AO and, possibly, the O2s with a small admixture of O2p AO, lies even deeper. Deep 1t₂ and 1a₁ MOs consisting mainly of the O2s AO are seen as low intensity long-wavelength maxima G and M respectively.

Consequently, much information on the MO structure of a chemical species under investigation can be derived from X-ray emission spectra.

Determination of the Effective Atomic Charges

The concept of the effective charge on atoms in molecules is known to be fundamental in the field of theoretical chemistry. It assumes that the entire electron distribution of an investigated atom can be considered as

Figure 3 Scheme of the sulfate ion MOs obtained from the full set of X-ray fluorescence spectra.

a point charge that coincides with the coordinates of the nucleus. This simple and obvious form of the electron density distribution in the examined species is rather approximate: in real molecules the outer electron shells of atoms substantially lose their ‘individuality’ because of the delocalization of valence electrons of atoms. The approximation procedure (the replacement of the real distribution of the outer electron density of an atom by the point charge on its nucleus) is not simple in general and depends largely on the actual definition of effective charge. A number of calculations and experimental methods used for the determination of the latter are known. The effective charges on atoms (q_A , where A is an element) do not belong to the class of directly observed physical characteristics, and therefore the so-called ‘experimental determination’ of q_A values usually means the result of the interpretation of various experimental data in terms of the corresponding model with q_A as a parameter.

Shifts of the energy of inner nl levels of the A atom (ΔA_{nl}), defined by X-ray photoelectron spectroscopy, are sensitive to q_A and the effective charges of all other atoms, and in terms of the so-called potential model can be written as

$$\Delta A_{nl} = k(A_{nl})q_A + \sum_{i \neq A} \frac{q_i}{r_{iA}} + \Delta E_r \quad [16]$$

where $k(A_{nl})$ is the coefficient that is characteristic of the A nl level, $\sum_{i \neq A} (q_i/r_{iA})$ is the Madelung potential and E_r is the relaxation energy. Shifts of inner $AK\alpha_1$ line ($2p_{3/2} \rightarrow 1s$ electron transitions are more intense than for $2p_{1/2} \rightarrow 1s$) and are determined by the difference between the shifts of one-electron energies of A1s and A2p_{3/2} levels:

$$\begin{aligned} \Delta AK_{\alpha_1} &= (E^{-2p} - E^{-1s}) - E_0^{-2p} - E_0^{-1s} \\ &= \Delta E^{-2p} - \Delta E^{-1s} \approx \Delta A_{1s} - \Delta A_{2p_{3/2}} \end{aligned} \quad [17]$$

where E_0^{-nl} is the total energy of the neutral A atom (A^0) containing a vacancy in the nl level.

The difference in the energy changes for different A_{nl} levels is rather small and therefore the $\Delta AK\alpha_1$ values are determined by subtraction of two large and very similar quantities, ΔA_{1s} and $\Delta A_{2p_{3/2}}$ (the energy shift of the A1s level always prevails over that of A2p_{3/2}). As a result, the $\Delta AK\alpha_1$ values are normally about ten times smaller than X-ray photoelectron A_{nl} shifts. However, $AK\alpha_1$ shifts have an obvious advantage. The corresponding electron transitions are localized in the same potential well as that created by the Coulomb field of other atoms of the system investigated. Hence, the potential model for $AK\alpha$ shifts, analogous to eqn [16], can be written as

$$\Delta AK_{\alpha_1} = k_A q_A \quad [18]$$

or, in a more universal form

$$\Delta AK_{\alpha_1} = f(q_A) \quad [19]$$

Many authors have investigated the dependencies of eqn [19] for different inner X-ray emission lines and atoms by different methods. Table 1 gives the $AK\alpha_1$ shifts for some phosphorus-, sulfur- and chlorine-containing compounds and q_A values obtained by the correlation of Mulliken charges calculated by the SCF *ab initio* method using a 4-31G** basis set for a sufficiently large series of A-containing molecules with the experimental $AK\alpha_1$ shifts.

Participation of the 3d Atomic Orbitals in L-Emission Spectra

From the X-ray L-emission spectra of S, Cl, P, within the framework of an MO method, one can estimate the 3d population. The basic problem is the need to calculate the matrix elements of the transitions $2p \rightarrow 3s$ and $2p \rightarrow 3d$. For $K\beta$ spectra of elements in period 3 in the dipole approximation, transitions are permitted from levels involving 3pAO, from which the MOs are constructed. The relative intensity of separate emission lines is proportional to the squares of the factors c_i^2 . In L-emission spectra of atoms in period 3 the MO coefficients arising from dipole rules of selection ($\Delta l = \pm 1$) will be simultaneously displayed MOs, which are constructed with participation of 3s AO and 3d AO. If the symmetry of a molecule is such that the MO of the systems can be constructed with simultaneous participation of 3s- and 3d AOs of a period 3 atom, the intensity of the emission line will depend on the contributions of both the 3d and the 3s AOs to the appropriate MO. Thus estimations of c_i^2

Table 1 Experimental $AK\alpha_1$ shift and q_A values

values with 3d AO and 3s AO from X-ray spectra need a knowledge of matrix elements of transitions $\langle 2p|r|3d \rangle$, $\langle 2d|r|3s \rangle$. The determination of such matrix elements becomes complicated by the problem of choosing a 'good' 3d wavefunction. It is known that the atomic 3d functions are too diffuse and their electronic density, appropriate to them, is located far from the nuclei of atoms and to be unsuitable for participation in chemical bonds. In the case of X-ray transitions the important behaviour of 3d wavefunctions is not in the area of valence electrons but in the field of core electrons of atoms, in particular in the area of 2p AO. The 2p AO wavefunctions are located near the nucleus of an atom and have atomic character. It is possible to consider that 3d AO in this area also has atomic character. On this basis the estimation of matrix elements $\langle 2p|r|3d \rangle$ and $\langle 2p|r|3s \rangle$ is carried out to account for the intensity of X-ray atomic transitions.

The analysis of spectra of molecules and ions shows that the short-wave maximum W in L-spectra of S and Cl (**Figure 2**) is basically connected with an MO, in which there is a significant contribution from the 3d AO, while the contributions of the 3s AO to these MOs are insignificant. The maxima V and M are connected with an MO in which the 3s AO participates. Hence, from L-spectra it is possible to obtain experimental values of the relative intensity of various lines and to determine the contribution of the AOs to the MOs.

Estimations for the ion SO_4^{2-} and the molecule SF_6 give I_{3d}/I_{3s} values that correspond to theoretical results. The consideration of results from sulfur- and chlorine-containing compounds indicates that the participation of 3d AO in various MO becomes appreciable. The study of shifts to $K\alpha$ lines over a range of molecules shows that the experimental relation I_{3d}/I_{3s} increases as the $K\alpha$ shift grows; physically this is connected to the growth of a positive charge on an atom of sulfur. **Table 2** gives the relative experimental 3d occupations for sulfur in some compounds.

Application of $\text{SK}\alpha$ Spectra to Characteristic Compounds

It is known that the energy of valence electrons of heteroatoms in periods 2 and 3 varies linearly with changes in the energy of their core electrons. The concept of an energy level of a hypothetical electron lone pair of a sulfur atom (hnS), whose energy depends only on the charge on the sulfur atom (q_s), has been suggested. The position of this level in the $\text{SK}\beta$ spectrum was related to the values of the $\text{SK}\alpha$ shift, which are proportional to the net charge on the sulfur atom. The following relationship was obtained by comparing the short-wave maximum in the SK spectra of saturated sulfides with the

Table 2 Relative 3d sulfur population from X-ray spectral data

Molecule	I_{3d}/I_{3s}	$\Delta E_{K\alpha,1,2}(\text{eV})$	q_s	$I\langle 2p r 3d \rangle / I\langle 2p r 3s \rangle$
$(\text{CH}_3)_2\text{SO}$	0.2	0.25	1.0	0.1
Cl_2SO	0.3	0.27	1.2	0.3

SO_4^{2-}	1.8	1.10	2.3	1.2

corresponding values of $\Delta(\text{SK}\alpha)$: $\text{hn}_s(K\beta)(\text{eV}) = E(n_s \rightarrow 1S_s) = 0.0056 \times 10^3 \Delta\text{SK}\alpha (\text{eV}) + 2468.37$, with $r = 0.973$, $s = 0.06$, $n = 26$.

Using the equation it is possible, knowing $\Delta\text{SK}\alpha$ values to predict the location of a hnS level in the $\text{SK}\beta$ spectra of any saturated sulfide compound. In fact, this level can be treated as a reference level in the analysis of the changes in the spectral structure caused only by orbital interactions devoid of the effect of charge changes on the sulfur atom. As an example one can consider the application for complex compounds with dimethyl sulfide.

It follows from **Figure 4** that the intensity of the short-wave maximum A, which in the $\text{SK}\beta$ spectra of sulfides corresponds to the transition from the nS level to the vacancy K of the sulfur atom, significantly decreases and is considerably shifted towards longer wavelength with respect to the hnS level ($K\beta$). This shift, $\Delta n_s = E_A(\text{SK}\beta) - \text{hn}_s(\text{SK}\beta)$ (**Table 3**), characterizes quantitatively the bonding nature of the highest occupied molecular orbital. The observed shift towards longer wavelength indicates that the nS level interacts with the vacant levels of the acceptor, being mainly of the d type. The differences in shapes of the $\text{SK}\beta$ spectra of the complexes studied (**Figure 4**) can be explained by the presence of partly populated valence d orbitals, apart from the vacant ones, in Ti, in contrast to Sn and Sb.

Application of $\text{SK}\beta$ and $\text{SK}\alpha$ Spectra for the Rodano-Group

It is known that the NCS-group in compounds can be coordinated with a metal in three ways: $\text{M}-\text{NCS}$ (a), $\text{M}-\text{SCN}$ (b) and $\text{M}-\text{NCS}-\text{M}$ (c). Inorganic thiocyanates with coordination of type (a) have a characteristically large (negative) total electronic density on the sulfur atom, lower intensity of long-wave maxima and lower energy of a short-wave maximum (**Figure 5**). In organic isothiocyanates the $\Delta\text{SK}\alpha$ values vary in an interval $-7400 - 5800 \text{ eV}$ with the intense short-wave maximum

A in the SK β spectra (E_A) in the range 2467.1–2467.8 eV. In organic thiocyanates these parameters become $\Delta SK\alpha = 4.7$ – $13.3 \text{ eV } 10^2$, $E_A = 2468.1$ – 2469.1 eV (Table 4). However, the ΔnS values of thiocyanates and

isothiocyanates are divided almost unequivocally: $\Delta nS \geq 0$ for thiocyanates, $\Delta nS < 0$ for isothiocyanates (in thiocyanates $3p\pi$ — electronic density of atom of sulfur enters into a strongly bonding MO). From the presence in the SK β spectra of thiocyanates (VI), (VII) of a single short-wave maxima A that is coincident with the level hnS , it follows that the level nS does not practically couple with the $\pi_{C\equiv N}$ orbitals. The existence of the advanced short-wave structure in SK β spectra of thiocyanates (VIII)–(X), beyond the hnS level, must relate to nS – π_{Ar} interactions. Thus, the spectra of thiocyanates (VIII)–(X) indicate two orthogonal conformations of the molecules, one in which nS – π_{Ar} interactions are absent giving rise to a peak coincident with the hnS level, and another in which the nS and π_{Ar} couple to give two maxima, A' and A'' , corresponding to levels $nS \pm \pi_{Ar}$.

Applications of K α Shifts for Electronic Density Redistribution

It was of interest to use the data obtained for the investigation of the electron density redistribution on complexation between a donor molecule PCl₃ or of SPCl₃ (where one can define the effective charges on all atoms by their K α shifts) and an acceptor molecule AlBr₃ containing no interfering atoms. The data presented in **Table 5** show that, in spite of a positive q_P growth on complexation, the total ligand electron density does not decrease (in the range of accuracy achieved) due to a strong dampening effect of the Cl atoms. This leads to a sufficient growth of the ionicity of all bonds of the ligands and acceptor. From **Table 5** it also follows that the positive charge on the central acceptor atom grows sufficiently on complexation while the electron density on acceptor geminal of atoms does not decrease.

Symbols

d	grating constant
I_A	fluorescence line intensity of an investigated element A
I_{st}	fluorescence intensity of a standard
n	order of spectrum
p_A	probability of a vacancy being filled without emission
p_r	probability of photon emission when vacancy is filled
U	X-ray tube voltage
V_i	ionization potential of the i th level
Z	atomic number
ε	electron kinetic energy
λ	wavelength
δ	shielding constant
ϕ	angle of incidence

General Characteristics

Development of the theory of the electronic structure of chemical compounds has revealed a great need for physical experimental methods to which modern methods of quantum chemistry can be applied. Primary information provided by quantum chemical methods of electronic structure studies concerns the energy spectrum of molecules as well as the structures of wavefunctions of molecular orbitals (MOs). There is a need for physical methods which would allow direct measurement of MO energies as well as the determination of the degree of participation of different atomic electrons in chemical bonding. X-ray emission spectroscopy (XES), which provides both integral information about electronic structure (effective charges on atoms, atomic orbital populations) and differential information (relative energies of occupied MOs and characteristics of their AO components), can be seen as an important approach.

X-rays, discovered by Röntgen in 1895, are a form of electromagnetic radiation that occupies the spectral area between UV and γ radiation in the range of wavelength $\lambda = 10^{-3} - 10^2$ nm, corresponding to energies $h\nu = 10-10^6$ eV ($\nu = c/\lambda$). X-ray spectroscopy is divided into

X-ray emission and X-ray absorption spectroscopy and is subclassified into short wavelength ($\lambda \leq 0.2$ nm), long wavelength ($0.2 \leq \lambda \leq 2$ nm) and ultralong wavelength ($\lambda > 2$ nm) regions.

X-ray emission spectroscopy is used for the study of electronic structure and for the qualitative and quantitative analysis of substances. With the help of X-ray emission spectroscopy one may investigate all elements of the periodic table (with $Z > 2$) in compounds and in any phase.

X-rays are divided into continuous and characteristic. Continuous X-rays occur as a result of the stopping of very fast charged particles (e.g. electrons) in the target substance and have a 'white' spectrum. Characteristic X-ray emission radiation is emitted by target atoms after their collisions with hot electrons (primary excitation) or with X-ray photons (secondary excitation, fluorescence radiation) and produces a line spectrum. These collisions may also remove an electron of any inner shell of a target atom. The resulting vacancy is filled by an electron transition from another inner or outer electron shell. As a consequence of this electron transition, energy is released which may be in the form of an X-ray quantum (Figure 1).

Characteristic X-Ray Emission Spectra

Characteristic X-ray emission spectra consist of spectral series (K, L, M, N...), whose lines have a common initial state with the vacancy in the inner level. Labels of basic X-ray transitions are shown in Figure 2. All electron levels with the principal quantum number n equal to 1, 2, 3, 4, etc. are named as K, L, M, N etc. levels and denoted

Figure 1 Scheme of radiation interaction with a substance.

Figure 2 Scheme of the most important X-ray emission transitions; n , l and j are correspondingly the principal, orbital and total quantum numbers of K, L_1 , L_2 , L_3 levels, etc.

with corresponding Greek letters and digit indexes. The electron transitions which satisfy the dipole selection rules

$$\Delta l = \pm 1; \Delta j = 0, 1 (j = \pm \frac{1}{2}); \Delta n \neq 0 \quad [1]$$

are most intense. The dependence of X-ray emission line energy on atomic number Z is defined by Moseley's law:

$$h\nu \sim (Z - \sigma)^2 \quad [2]$$

where Z is the atomic number and σ is the shielding constant, which varies from series to series. Therefore, any X-ray emission spectral line is the finger-print of an element.

With X-ray emission excitation by electron bombardment (primary emission) all emission lines of the i th series appear when the X-ray tube voltage U exceeds the ionization potential of the i th level (V_i). At higher U the intensity of all lines of the i th series, I_i , increases because the electrons penetrate deeper into the target substance and, therefore, the number of excited atoms in the target increases. In the $V_i < U < 3V_i$ region, the intensity obeys the rule $I_i \sim (U - V_i)^2$. With a further increase in U X-ray emission begins to be absorbed by the target atoms; therefore the increase in I_i is reduced. At $U \geq 11 V_i$, I_i decreases because now most of the excited atoms are so deep in the target that their emitted radiation is absorbed by the target substance.

X-ray emission spectra are usually excited by X-ray photons because most chemical compounds are decomposed by electron bombardment. With X-ray emission spectra excitation by photons [secondary emission or fluorescence (XFS)] the fluorescent line intensity depends on the exciting photon energy $h\nu$ and $I_i = 0$ if $h\nu < V_i$. All lines of the i th series appear if $h\nu = V_i$;

however, I_i decreases little with further increase in $h\nu$. Therefore, to excite X-ray fluorescence one must use a target that contains a substance with intense characteristic X-ray lines whose energy just exceeds eV_i . Using the continuous radiation of an X-ray tube with a target consisting mostly of heavy elements it is possible to excite X-ray fluorescence.

The intensity of a characteristic X-ray spectrum (both primary and fluorescent) depends on the probability p_r of a radiation transition in the atom having the vacancy in the i th level. The value of p_r is determined by the total probability of photon emission when this vacancy is filled by outer electrons. However, with a probability p_A the vacancy may be filled by outer electrons without radiation as the result of the Auger-effect (see Figure 1). For the K series of medium and heavy elements $p_r > p_A$, for the light elements $p_r < p_A$. For all other series of any elements $p_r \ll p_A$. The ratio $f = p_r / (p_r + p_A)$ is called the yield of characteristic radiation.

However, X-ray characteristic lines appear because of single atom ionization; in X-ray emission spectra weaker lines are found to occur as a result of binary (or multiple) atom ionization when two (or more) vacancies are formed simultaneously in different electron shells. If, for example, one vacancy is formed in the K shell of atoms and filled by electrons belonging to the $L_{2,3}$ shell, atoms emit an $\hat{E}\alpha_{1,2}$ doublet. If another vacancy is formed simultaneously which too is filled by electrons from the $L_{2,3}$ shell, then the final state will have a binary ionization $L_{2,3}L_{2,3}$, and would correspond to the emission of radiation with energy exceeding that of the $\hat{E}\alpha_{1,2}$ doublet. As a result, in an X-ray emission, spectrum a short wavelength $\hat{E}\alpha_{3,4}$ doublet, called a satellite of the main $\hat{E}\alpha_{1,2}$ doublet, would appear. Because of such processes of multiple ionization X-ray emission, spectra may have a large number of satellites of the main lines. Usually, the satellite intensity is some orders of magnitude less than that of the main lines. However, if target atoms are bombarded by heavy ions with great energy, the probability of multiple atom ionization becomes higher than that of single ionization. Therefore, in this case the intensity of the main emission lines is essentially less than that of the satellites.

The Continuous X-Ray Spectrum

The continuous X-ray radiation occurs because of electron deceleration in the target substance. Electron energy losses by radiation have quantum character, the emitted photon having an energy $h\nu$, which cannot exceed the electron kinetic energy ε , i.e. $h\nu \leq \varepsilon$. The energy $h\nu_i = \varepsilon$ is called the quantum boundary of a continuous spectrum. The corresponding wavelength λ_i depends on the X-ray

tube voltage charge U as follows:

$$\lambda_i(\text{nm}) = hc/(eU) = 1239.8/U(V) \quad [3]$$

At $\lambda < \lambda_i$ the intensity of continuous radiation is absent. With an increase in λ from λ_i to $3\lambda_i/2$ the continuous radiation intensity increases and with further increases in λ it decreases.

X-Ray Sources

The most widespread source of X-rays is the X-ray tube. In an X-ray tube, electrons emitted from the cathode are accelerated by an electrical field and bombard the metal target (anode). Target atoms, excited by electron impact, and electrons losing their kinetic energy when decelerating in the anode substance, emit X-rays. The primary radiation of the X-ray tube consists of two parts – characteristic (line) and continuous radiation. As a result of the primary radiation impinging on a substance its atoms emit characteristic fluorescence (secondary) radiation.

Other sources of X-rays are radioactive isotopes which can directly emit X-rays or electrons or particles. In the last two cases charged particles can bombard the target substance which then emits X-rays. The intensity of X-ray isotope sources is some orders of magnitude less than that of X-ray tubes; however the dimensions, weight and cost of X-ray isotope sources are less than that of X-ray tubes.

X-rays are also generated as synchrotron radiation. It can be selected by a crystal analyser and may be used as an X-ray source. The intensity of X-rays selected from synchrotron radiation is some orders higher than that from an X-ray tube.

The characteristic radiation of the X-ray tube is spread in space isotropically, whereas its continuous radiation has maximal intensity in directions in a plane perpendicular to the trajectory of electrons bombarding the target. The X-ray component of synchrotron radiation is polarized and spread only in the plane of the synchrotron ring.

Obtaining X-Ray Emission Spectra

A schematic of an X-ray fluorescence instrument is presented in **Figure 3**. The X-ray tube is used as the source of primary radiation $h\nu_1$. The vacancies in inner shells of atoms of the substance investigated are formed as a result of primary radiation action. These vacancies are filled by other inner or outer electrons. This is accompanied by X-ray fluorescent photons $h\nu_2$ being emitted. This fluorescence radiation is spread out into

Figure 3 An X-ray fluorescence spectrometer. 1, X-ray tube; 1a, electron source; 1b, target; 2, substance investigated (secondary anode); 3, crystal analyser; 4, registration device; $h\nu_1$, primary radiation; $h\nu_2$, secondary radiation; and $h\nu_3$, registered radiation.

the spectrum by means of a crystal analyser (or, for the ultrasoft X-ray region, by means of diffraction gratings) in accordance with Bragg's law

$$2d\sin\phi = n\lambda \quad [4]$$

where n is the order of the spectrum, λ is the wavelength, d is the grating constant of the crystal analyser and ϕ is the angle of incidence of the collimated X-ray fluorescent beam on the specific set of parallel planes in the crystal from which the beam is diffracted (see **Table 1**).

The X-ray fluorescence spectrum is then registered on a photographic film or by Geiger, proportional or scintillation counters, semiconductor detectors, etc. The wavelengths and energies of the characteristic emission lines have been accurately measured and tabulated in handbooks, monographs and reference works for all chemical elements with $Z > 2$.

X-Ray Fluorescence Analysis

X-ray fluorescence analysis (XFA) is based on the X-ray emission line's intensity dependence on the concentration of the appropriate element. XFA is widely used for the quantitative analysis of various materials, especially in black and colour metallurgy and geology. XFA is distinguished by rapidity and a high degree of automation. The detection limits depend on the element, matrix composition and spectrometer used and lie in the region 10^{-3} – $10^{-10}\%$. Defining any element (with $Z > 4$) is possible by means of XFA in both a solid and a liquid phase.

However, the fluorescence line intensity I_A of an investigated element A depends not only on its concentration

Table 1 Parameters of typical crystal analysers

C_A in the sample, but also on the concentration of other elements, C_b , because other elements promote both absorption and excitation of fluorescence of the element A (matrix effect). Moreover, the measured value I_A essentially depends on the sample surface, phase distribution, grain sizes, etc. Numerous methods have been developed to account for such effects. Most notable are the empirical methods of external and internal standards, using the background of scattered primary radiation and the method of dilution.

In the external standard method the unknown concentration C_A of the element A is determined by comparing the intensity I_A in the sample investigated with analogous I_{st} values of standards for which defined element concentrations C_{st} are known:

$$C_A = C_{st}I_A/I_{st} \quad [5]$$

This method allows one to take into account corrections connected with the equipment used; however, the composition of the standard should be close to that of the investigated sample to precisely match the matrix effect.

In the internal standard method some amount $\Delta\tilde{N}_A$ of a defined element A is added to the sample investigated. This leads to an increase in the fluorescence intensity of ΔI_A . In this case:

$$C_A = I_A\Delta C_A/\Delta I_A \quad [6]$$

This method is especially effective for the analysis of complex samples but needs the special requirements of sample preparation.

The use of the background of scattered primary radiation is based on the fact that the ratio $I_A:I_b$ (I_b is the background intensity) mainly depends on C_A and only weakly depends on the concentration of other elements, C_i .

In the method of dilution a great amount of a weak absorber or a small amount of strong absorber is added to the sample investigated. These additions should reduce the matrix effect. This method is effective for water solution analysis and for the analysis of complex samples when the internal standard method is inapplicable.

There are also models in which the measured intensity I_A is corrected on the basis of the intensities I_i and concentrations C_i of other elements. For example, C_A may be represented as:

$$C_A = a_{A0} + a_{A1}I_A + a_{A2}I_A^2 + I_A \sum_{m,i} m_{Ai}I_i + \sum_{m,i} b_{Ai}I_i + \sum_{m,i} d_{Ai}I_i^2 (i \neq A) \quad [7]$$

where a and b are values determined by the least-squares method with the help of I_A and I_i values measured in several standards with known concentrations C_A of element A. Such models are widely used for the computerized serial analysis of many samples.

X-Ray Microanalysis

X-ray microanalysis is a local analysis, fulfilled by means of a microanalyzer electron probe, for sample sites of $\sim 1\text{--}3\text{ }\mu\text{m}^2$. The electron probe is formed by electrostatic and magnetic fields to obtain a parallel electron beam with a diameter of $\sim 1\text{ }\mu\text{m}$. The analysis is via primary X-ray sample emission which is spread out into a spectrum by means of the X-ray spectrometer. In this method corrections for the atomic number of the element, the absorption of its radiation in the sample, its fluorescence, and the characteristic spectra of other elements contained in the sample must be accounted for. Microanalysis is used for the investigation of two- and three-component systems such as mutual diffusion, crystallization processes, local variations of alloy structure, etc.

Symbols

A	atomic mass
b_i	calibration coefficient for element i
c_i	concentration of element i
C_j	concentration of element j
d	d-spacing of a crystal
$d_{1/2}$	half absorption thickness
D_∞	saturation thickness
e	charge of an electron
E	initial energy of the photon
E_0	maximum energy of accelerated electron
E_∞	energy necessary to remove an electron from the orbital n
E'	photon energy after Compton scattering
E_e	energy equivalent of the electron mass or energy necessary to produce an electron-ion pair
E_{final}	final energy of the transferred electron
E_{initial}	initial energy of the transferred electron
E_{photon}	energy of the emitted photon
F	Fano factor
i	tube current
I	radiation intensity
I_{Cref}	intensity of reference Compton peak
I_{Csample}	intensity of sample Compton peak
I_F	intensity of fluorescence radiation
I_i	radiation intensity element
k	constant
k'_{ij}	coefficient for absorption correction
k''_{ij}	coefficient for enhancement effect
m'_{ij}	inter-element coefficient for absorption and enhancement
m''_{ij}	coefficient for line interference
n	principal quantum number or order of diffraction
N	number of electrons or number of ionizations per photon
U_0	acceleration voltage
Z	atomic number
Z_{eff}	effective atomic number
α_{crit}	critical angle of total reflection
α_{ij}	correction coefficient for interelement matrix effects

Θ	angle between primary and secondary radiation
μ	mass attenuation coefficient
λ	wavelength of radiation
ρ	density
σ	standard deviation

X-ray fluorescence (XRF) spectrometers are widely used for the determination of elements with atomic numbers from 4 (beryllium) to 92 (uranium) at concentrations from $0.1 \mu\text{g g}^{-1}$ to high percentage levels. These elements can be analysed using characteristic K_α -lines (KL_{III}) from 11.4 nm/0.1885 keV (Be K_α) to 0.0126 nm/98.4 keV (U K_α). Nevertheless, elements of higher atomic number (e.g. Cd $\text{L}_{\text{III}}\text{M}_{\text{V}}$ 0.3956 nm/3.133 keV; U $\text{L}_{\text{III}}\text{M}_{\text{V}}$ 0.09106 nm/13.61 keV) are often determined using their L-lines. The characteristic X-ray lines of these elements can be determined either with sequential or with simultaneous wavelength-dispersive spectrometers by Bragg diffraction, using the wave phenomena of X-rays or in energy-dispersive systems using their energy characteristic. Coherent and incoherent scattering of primary X-rays in the sample may cause increased background effects, and matrix-dependent absorption of the characteristic secondary X-rays may also cause severe matrix effects. Since XRF methods are routinely used, methods for correcting the matrix effects such as fundamental parameters have been developed and instruments with drastically improved peak to background ratios such as polarized X-ray fluorescence (PXRF) and total reflection X-ray fluorescence (TXRF) spectrometers were designed during the 1990s. The principles of XRF spectroscopy and descriptions of the different kinds of instrumentation are given in an increasing number of monographs, books and reviews, with extensive data compilations.

Principles

If a target is irradiated with photons, or charged particles (electrons or ions) with energies exceeding the binding energy of the bound inner electrons, an electron from inner orbitals of the target atoms can be ejected.

$$E_\infty = 13.56 \cdot \frac{[Z_{\text{eff}}]^2}{n} \text{ (eV)}$$

where Z_{eff} = effective atomic number and n = principal quantum number. If the total energy of the photon is transferred to the electron, this interaction is called the photoeffect.

The resulting atom is unstable and regains its ground state by transferring an electron from a high-energy outer orbital to the vacancy in the inner electron shell. The energy difference between the initial and final energy state of the transferred electron is released as a photon of the energy

$$E_{\text{photon}} = E_{\text{initial}} - E_{\text{final}}$$

In XRF spectroscopy photons are used to excite the characteristic elemental X-rays from the sample. Alternatively the incident photons can be scattered coherently (Rayleigh scattering) at an electron of the inner shell or incoherently at an electron of the outer shell (Compton scattering). In the second case the wavelength/energy of the scattered photon depends on the initial wavelength/energy of the original photon and the scattering angle Θ

$$E' = E/[1 + (1 - \cos\Theta)(E/E_e)]$$

where E' = photon energy after Compton scattering, E = initial energy of the photon and E_e = energy equivalent of the electron mass. The XRF spectrum of a sample is a mixture of the different characteristic X-rays emitted from the atoms in the sample and of coherent and incoherent scattered components of the primary radiation source. The task of XRF spectrometers is to separate the different spectral components, to determine their intensities and based on this to calculate the elemental concentrations. Typically, XRF spectrometers consist of a photon source for the excitation of the secondary X-rays, a sample support, an X-ray detection unit and a data evaluation unit.

X-Ray Sources

In most XRF spectrometers an X-ray tube is used as the photon source. Alternatively radioactive isotopes can be applied for the excitation of the characteristic X-rays from the sample. X-ray tubes can be used in both wavelength-dispersive and energy-dispersive systems. Due to their lower beam intensities, application of radionuclides is restricted to energy-dispersive systems.

X-Ray Tubes

In X-ray tubes, the X-rays are produced by the bombardment of matter with accelerated electrons. The X-ray tubes are built as a vacuum-sealed metal glass cylinder. The electrons are emitted from a heated tungsten filament which serves as the cathode and are

accelerated by a high voltage applied between the filament and a metal anode. Two effects can occur if the accelerated electrons interact with the atoms of the anode material. (1) An electron enters the electric field of an atomic orbital and is slowed down, and the loss of kinetic energy during slowing down is emitted as electromagnetic radiation, called bremsstrahlung. (2) An inner-shell electron of an atom is ejected if the kinetic energy exceeds the binding energy, and from this the characteristic X-rays of the anode material are emitted. Thus the spectrum emitted from the anode consists of the continuous bremsstrahlung and the characteristic X-ray lines of the anode material.

The maximum X-ray energy primarily emitted from the tube is determined by the applied acceleration voltage.

$$E_0 = e \cdot U_0$$

The radiation intensity is a function of the tube current and the applied high voltage (**Figure 1**).

$$I(\lambda)d\lambda = kiZ\left(\frac{\lambda}{\lambda_0} - 1\right)\frac{1}{\lambda^2}d\lambda$$

Excitation of the characteristic X-rays from the sample can be optimized by selecting the appropriate anode material, voltage and tube current (**Table 1**).

In wavelength-dispersive XRF (WDXRF), TXRF and PXRF methods, efficiencies of primary-to-detected-secondary radiation are very low. Therefore tubes for these methods are generally operated at high power [~ 3 kW per kV up to 100 kV]. Because most of the tube power is converted to heat, these tubes have to be water cooled. Depending on the kind of application, different tube designs such as end-window (e.g. **Figure 9**), side-window (**Figure 2a**) and line focus are employed. When extremely high primary intensities are necessary rotating anodes are used (**Figure 2b**). In energy-dispersive systems radiation efficiency is several orders of magnitude higher than in WDXRF; therefore compact air-cooled low-power tubes (3–100 W) are used in most cases.

Figure 1 Primary spectrum of an X-ray tube with a rhodium anode.

Table 1 Anode materials and application ranges of X-ray tubes used for X-ray fluorescence analysis

Anode material	Element range		Operating voltage (kV)
	K-spectra	L-spectra	
Cr	^8O – ^{22}Ti	^{42}Mo – ^{55}Cs	55
W	^{23}V – ^{27}Co	^{56}Ba – ^{72}Hf	55

Mo	^{31}Ga – ^{39}Y	^{76}Os – ^{92}U	100
Rh	^{4}Be – ^{56}Ba	^{42}Mo – ^{92}U	60

Radionuclide Sources

In mobile EDXRF systems, where small dimensions are essential, sealed radionuclides are often used as primary radiation sources instead of X-ray tubes. The radionuclides have to be selected with respect to their decay scheme, half-life and radiotoxicity (Table 2).

β^- Decay

From isotopes decaying in β^- -mode, high-energy electrons ranging from several keV to MeV are emitted from the nucleus. The electrons interact with the matter and bremsstrahlung is produced. Most β^- -sources are used for secondary target excitation.

Electron Capture (EC)

The nucleus captures an electron of the innermost electron shell and a proton of the nucleus changes into a neutron. Due to this process a vacancy in the innermost electron shell occurs. By filling this vacancy with an electron from the outer shells, the characteristic X-rays of the daughter atom are emitted.

γ Decay

In most of the radioactive decays the daughter isotope is formed in an excited state. These nuclides are transferred into the ground state by emitting electromagnetic radiation, the γ -radiation.

Selection Criteria

The choice of the radionuclide source depends on the type of sample, the elements to be determined and the detection technique. Generally a high specific activity of the radionuclide and emission energies suitable for the application are required. The most convenient isotopes for energy-dispersive XRF are those that decay exclusively by EC without emitting γ -radiation.

Radionuclides emitting high-energy photons (>150 keV), or decaying by β^+ or high-energy β^- , or those with short half-lives are not recommended for use in XRF

systems. A selection of suitable radionuclides with suitable energies and high specific activity is given in Table 2.

X-Ray Dispersion and Detection Units

XRF spectrometers have two major objectives: (a) to determine the spectral distribution of the X-rays emitted from the sample; (b) to measure the intensity of the selected spectral component. In wavelength-dispersive XRF, the spectrum is dispersed into different wavelengths by Bragg diffraction at different crystals. Intensities are measured by electronic detectors. In energy-dispersive spectrometers both energy dispersion and intensity measurement are performed by electronic detectors; thus for detectors used in energy-dispersive spectrometers extremely good energy resolutions are required.

Dispersing Crystals

At the X-ray diffraction crystals the X-ray spectrum is dispersed into different wavelengths according to Bragg's law

$$n \cdot \lambda = 2d \sin \Theta$$

Table 2 Radionuclides used as primary sources in energy-dispersive X-ray fluorescence

Isotope	Decay mode	Half-life (years)	Energy (keV)	Elemental range		Recomm. activity (MBq)	Working life (years)

The wavelengths of characteristic lines used in X-ray spectrometry range from ~ 0.03 nm (Ba K) to ~ 10 nm (Be K). This range cannot be covered by use of a single diffraction crystal. The detectable wavelength and high-order reflections are limited by the relation between d and λ .

$$n\lambda \leq 2d$$

For example with LIF 200, the crystal with the broadest application range, the elements with atomic numbers < 19 (K) are not detectable. At shorter wavelength, the dispersion between neighbouring lines decreases and they cannot be resolved from each other. The diffraction crystals have to be selected with respect to their reflectivity and to be suitable for the lines to be detected. Commonly used X-ray diffraction crystals and their application range are compiled in **Table 3**.

X-Ray Detectors

In X-ray detectors the energy transported by the radiation is converted into forms that can be recognized visually or electronically. Generally the photons are absorbed by the detector material and energy transfer takes place by ionization. The number of ionizations N per photon is proportional to the energy E of the absorbed photon and depends on the average energy e necessary to produce an electron–ion pair in the detector material.

$$N = E/e$$

The energy resolution of a detector is determined by the statistical scatter of the number of ionizations per photon.

$$\sigma = \sqrt{(FN)}$$

with F = the Fano factor. Due to this relation it is possible to separate the radiation absorbed in the detector into the different energies.

Critical parameters for selection of an appropriate detector are: efficiency, energy resolution and dead-time, i.e. the pulse processing time of the detector. A measure for the energy resolution is the full width of half maximum (FWHM).

$$\text{FWHM} = 2.36 \times \sqrt{(eFE)}$$

The detector efficiency depends on the radiation energy to be determined and the density and type of detector material. In XRF spectrometers three different types of X-ray detectors are used: gas-filled detectors, scintillation detectors and semiconductor detectors.

Gas Proportional (Flow-) Counters

Gas-filled detectors are used for the determination of low-energy X-rays. An isolated thin wire is mounted in a metal cylinder filled with a suitable counting gas (e.g. 10% Ar, 90% CH₄). The wire is held at a high positive potential (1.2–2 kV) and the metal cylinder is grounded (Figure 3). A thin window (Be or Mylar) allows the radiation to enter the detector. The gas is ionized by the photons and the electrons produced are accelerated towards the anode and the ions towards the cathode. The energy necessary to produce an ion pair is 20–30 eV, depending on the type of counting gas. Additional ionizations are produced by collisions with other gas atoms. The electrons are collected at the anode, producing a short-term voltage drop. Applying an appropriate high

Figure 3 Schematic of gas proportional counter (flow counter) and scintillation detector operated as tandem detectors in wavelength-dispersive X-ray fluorescence spectrometers. R = resistor; C = capacitor.

voltage to the detector, the voltage drop is proportional to the radiation energy (Figure 4). High radiation doses degrade the counting gas. In addition, the thin detector windows, necessary for the detection of low-energy photons, can lead to a permanent loss of counting gas by diffusion. To avoid these problems the detectors are operated as flow counters, in which the counting gas is permanently exchanged.

Scintillation Detectors

Scintillation detectors are used for the determination of the high-energy part of the X-ray spectrum. In scintillation detectors the material of the detector is excited to luminescence (emission of visible or near-visible light photons) by the absorbed photons or particles. The number of photons produced is proportional to the energy of the absorbed primary photon. The light pulses are collected by a photo-cathode. Electrons, emitted from the photocathode, are accelerated by the applied high voltage and amplified at the dynodes of the attached photomultiplier (Figure 3). At the detector output an electric pulse proportional to the absorbed energy is produced. The average energy necessary to produce one electron at the photocathode is approximately 300 eV. For X-ray detectors, in most cases NaI or CsI crystals activated with thallium are used. These crystals offer a good transparency, high photon efficiency and can be produced in large sizes.

Semiconductor Detectors

Semiconductor detectors can be considered analogous to ionization chambers with the gas being replaced by the semiconductor material. The group 4 elements silicon and germanium are most widely used as semiconductor detectors when excellent energy resolution is required. Semiconductors have a small energy gap between their valence and conducting bands. At energies above

Figure 4 Gas-amplification characteristics of gas-filled detectors. Most flow counters for WDXRF are operated in the changeover region from proportional to Geiger-Müller.

absolute zero, thermal excitation will move some electrons from the valence band to the conductor band and holes or positive charges are left in the valence band. The quasi-free electrons in the conductor band move towards the anode if an electric field is applied. If ionizing radiation interacts with a semiconductor, electrons are transferred from the valence to the conducting band. The energy necessary to produce an ion pair is low (3–5 eV). Thus a large number of electrons, proportional to the absorbed radiation energy, can be collected at the anode by applying a high voltage of 1–2 kV to the detector, and statistical scatter is low. The current of the radiation-induced free electrons is superimposed by the temperature-dependent free charge density (leakage current) and electron recombination by acceptor-type impurities. Silicon cannot be produced at purity levels that allows electron recombination by acceptor-type impurities to be neglected. In Si(Li) detectors acceptor-type impurities are compensated for by drifting the silicon with lithium as donator.

In order to reduce the thermal charge carrier generation (noise) to acceptable levels Si(Li) detectors and Ge detectors are operated at liquid nitrogen (LN₂) temperatures. LN-cooled detectors are mounted in a vacuum chamber, which is inserted in or attached to an LN₂ Dewar flask (Figure 5). The detector is in thermal contact with the LN₂ and the radiation enters the detector housing via a thin Be window. In mobile systems, and for applications requiring long-term unattended operation, detectors cooled by Joule–Thomson coolers, He-cycle refrigerators or Peltier elements are used, but all of them can show degraded energy resolution, with the Peltier exhibiting the most (~20%). Extremely compact room

temperature detectors using semiconductors with higher energy gaps (CdZnTe, HgI₂, GaAs) have been developed in the 1990s. Energy resolution of these detectors is poorer than for Si(Li) detectors but better than with proportional or scintillation detectors. The characteristic properties of the different detector types are compared in Table 4.

Wavelength-Dispersive Spectrometers

In wavelength-dispersive spectrometers the characteristic radiation emitted from the sample is dispersed into different wavelengths by Bragg diffraction and the resulting radiation is registered by electronic detectors. Since the wavelength selection is performed by diffraction of the radiation to different angles, only minor energy resolution of the radiation detectors is required. Nevertheless according to Bragg's law, higher order diffraction radiations of the wavelength $\lambda/2$, $\lambda/3$, etc. are registered at the same angle as those of wavelength λ . These high-order signals cannot be separated by the diffraction crystals, but they are significantly different in their energies and can be separated using the energy-resolution capabilities of the detectors. Figure 6 gives an example of elimination of second-order radiation by energy discrimination in WDXRF.

Thus, a wavelength-dispersive spectrometer consists of the excitation unit (X-ray tube with high-voltage supply), the sample chamber, the diffraction unit and the detector unit with amplifier, lower level and window discriminator, and registration unit (Figure 7). Generally the sample, the diffraction unit and the low-energy detector are mounted together in a vacuum chamber to avoid absorption of low-energy X-rays along the radiation path. For some applications, primary beam filters are used to optimize the tube spectrum. Wavelength-dispersive spectrometers are either designed as fixed (simultaneous) spectrometers or as sequential (scanning) spectrometers. Generally wavelength-dispersive spectrometers have a mass of > 400 kg and are operated in well-established laboratories, equipped with cooling water facilities and high-current electric power supply. Nevertheless, mobile systems operated with low power tubes are also possible.

Sequential Spectrometers

In most sequential XRF spectrometers a flat crystal is mounted on the central axis of a rotating goniometer and a proportional counter and a scintillation counter are mounted at the moving goniometer arm. The Bragg angle can be simply varied, rotating the crystal mount by Θ and the detectors by 2Θ . Primary and secondary collimators between sample and crystal and crystal and detectors are used to limit the beam divergence. Most common types

Figure 5 Schematic of a planar semiconductor detector. HV = high voltage; FET = field-effect transistor.

Table 4 Properties of radiation detectors used in XRF systems

Detector type	Material/filler gas	Ionization energy (eV)	Band gap (eV)	FWHM at 5.9 keV (eV)		Dead-time (μ s)	Energy range (keV)	Remarks
				Theor.	Typical			
Proportional counter	Ar/methane	26.4		840	840	1	< 1–10	
Scintillation	NaI(Tl)	300		3150	3150	0.2	3–100	
Semiconductor	Si(Li)	3.61	1.12	120	150	2–4	1–60	LN ₂
	Ge	2.98	0.74	108	145		1–200	LN ₂
	CdZnTe	~5	~1.5	135	285		> 2	
	HgI ₂	6.5	2.13	160	270		> 2	

**Figure 6** Wavelength and energy spectrum of Ni K α in the presence of high Rb concentrations with open window (3 V) and window width set to 1.3 V to remove second-order radiation of Rb K β . Spectrum of reference rock MA-N, measured with WDXRF SRS 303 AS.

of collimator consist of a pack of parallel plates of highly absorbing material (e.g. tungsten). Radiation (nearly) parallel to these plates can pass, whereas diverging radiation is absorbed by the plates. Narrow spacing of the plates results in optimum resolution but intensity is reduced by an amount equivalent to the space angle (Figure 8). Therefore most sequential spectrometers are equipped with coarse and fine spaced primary collimators.

Curved focusing scanning crystals are rarely used in wavelength-dispersive instruments, but are common in microprobes.

Simultaneous Spectrometers

Simultaneous spectrometers are designed with fixed crystal arrangements. In modern simultaneous spectrometers up to 30 crystal-detector combinations are fixed at suitable angle positions for the peak and background measurements of the application. Generally, focusing crystal shapes are used. For fixed diffraction geometries the best focusing is achieved with logarithmically curved crystals (Figure 9).

Energy-Dispersive Spectrometers

In energy-dispersive systems the separation of the different components in the X-ray spectrum is performed exclusively by the detector and the subsequent electronic components. Thus good energy resolution, low electronic noise, low temperature drift and excellent linearity of the electronic components are required. Generally, an energy-dispersive spectrometer consists of a radiation source (X-ray tubes or radionuclides), sample support, pre- and main amplifier, pile-up rejector, analogue-to-digital converter and multichannel analyser.

As radiation sources, X-ray tubes or radionuclides are applied. The polychromatic radiation of the tube is scattered by the Compton or Rayleigh effect towards the detector, which results in a high bremsstrahlung background and line interferences caused by the characteristic lines of the anode material and the resulting Compton peak.

Primary beam filters are used routinely in energy-dispersive XRF (EDXRF) to optimize the tube spectrum for the specific application (Figure 10). Filters with a sharp absorption edge slightly above the characteristic tube lines are used for filtering out the high-energy bremsstrahlung and a quasi-monochromatic excitation spectrum is achieved (e.g. Rh tube and Pd filter). The characteristic lines can be removed by heavy-element filters without an absorption edge in the high-energy region (e.g. Rh tube and Cu filter) (Figure 11). The use of primary beam filters causes some intensity loss but this is overcompensated for by the background reduction.

Secondary targets are used to provide optimal excitation conditions for specific elements, but the drastic loss of intensity in the beam restricts their application to tubes with higher output powers or radionuclides of higher activities. Most radionuclides provide monoenergetic excitation, but the excitation energies are not tunable. For radionuclide sources a licence for handling and transportation is required.

In EDXRF systems, semiconductor detectors are used exclusively, apart from some mobile systems for low-energy application equipped with high-resolution

Figure 8 Schematic of coarse and fine collimator assignment.

proportional counters. Most systems are equipped with cooled Si(Li) or Ge detectors. The energy-proportional electric charge pulse is integrated by the preamplifier. Today state-of-the-art preamplifiers are of the pulsed optical feedback type with the first active element, a field-effect transistor (FET), mounted in the detector cryostat in order to reduce electronic noise. The preamplifier output is converted to an energy-proportional voltage pulse of some microseconds duration, depending on the shaping time of the amplifier. Events arriving at the detector and amplifier during their signal processing period cannot be processed correctly. A pile-up rejector eliminates these pulses by inspecting the slopes of the pulses. The amplifier output signal is digitized by a subsequent analogue-to-digital converter (Wilkinson type) and collected in the memory of a multichannel analyser. Each channel is equivalent to a small energy interval and the channel content holds the counts of this energy interval, accumulated during the measuring time. All spectral components are registered simultaneously.

EDXRF systems are available as stationary systems, to be used for fast simultaneous multielement determinations in analytical laboratories, as compact equipment suitable for mobile field laboratories and as hand-held probes to be

used directly on-site for screening analyses. The dimensions of the equipment range from several hundred kg for stationary systems down to 1.3 kg for the smallest radio-nuclide-excited hand-held probe.

Special instruments have been developed for trace element analysis in the picogram region in microsamples using total reflection of the X-ray beam (TXRF) and the sub- $\mu\text{g g}^{-1}$ range in bulk samples using polarized X-rays.

Total Reflection XRF (TXRF)

At radiation incident angles of less than the critical angle α_{crit} , the primary beam is totally reflected at the surface of a specimen.

$$\alpha_{\text{crit}} \approx \frac{1.65}{E} \sqrt{\frac{Z}{A} \rho}$$

where ρ = density, A = atomic mass and Z = atomic number. At angles $< \alpha_{\text{crit}}$ the X-rays can penetrate into the substrate only for a few nm. At these angles interaction of the X-rays with the total reflecting specimen is at a minimum. This effect is used in two types of TXRF instruments. In total reflection devices for trace element analysis, the sample is prepared as a thin film on a well-polished quartz block. In conventional thin film methods the characteristic X-rays of elements in the sample are excited, but excitation and Compton scattering occurs within the material of the sample support as well. In TXRF the geometry is arranged to provide a total reflection of the primary X-ray beam (Figure 12). The low total reflecting incident angle provides an excellent interaction between the primary beam (absorption path $\sim 1 \text{ mm}$ per $1 \mu\text{m}$ sample thickness) and the sample, whereas absorption of the secondary radiation in the sample can be neglected in most cases. Generally, it is not

necessary to use matrix correction methods as it is with other XRF methods. Once calibrated, samples of all the matrices can be analysed without recalibration and matrix corrections. Detection limits at the $\mu\text{g g}^{-1}$ level can be obtained from a few micrograms of solid sample and at the ng g^{-1} level from a few microlitres of a liquid sample. For surface and thin layer analysis, instruments with angle variable sample positioning devices are used. With these instruments the angle-dependent intensity profile can be recorded as the basis for surface and thin layer analysis. For the determination of thin layer and surface contaminations, e.g. for wafer analysis, the measurement is performed at the critical angle with the

beam grazing the surface. With these devices impurities of some $10^{11} - 10^{13} \text{ atoms cm}^{-2}$ can be determined.

Polarized X-Ray Fluorescence (PXRF)

In PXRF the primary X-ray beam is polarized by Barkla scattering or Bragg reflection. Under orthogonal conditions the scattered radiation is highly polarized. The polarized radiation is used to excite the characteristic X-rays of the elements in the sample. The secondary radiation is measured in orthogonal geometry to the polarization plane. Background, produced by Compton and Rayleigh

Figure 11 Energy-dispersive spectra of reference soil sample GXR-2, measured with Spectrace 5000 using an Rh anode tube and Pd and Cu primary beam filters to optimize excitation conditions.

Figure 12 Schematic of TXRF and x – y – z geometry of PXRF.

scattering in the sample, is effectively reduced. Detection limits in bulk samples are improved by approximately a factor of 3 compared to normal EDXRF. Thus sensitivity and accuracy are equivalent (K–Mo, Hf–U) or better (Ag–Nd) than those obtained by WDXRF. Therefore, PXRF combines the capability of nondestructive multielement analysis with low detection limits and a minimum of sample preparation.

Sample Preparation for XRF

With XRF solid as well as liquid samples can be analysed. Liquid samples have to fill an adequate sample container, with an X-ray transparent window (e.g. Mylar). For the determination of light elements the sample chamber has to be flushed with He instead of applying a vacuum. Solid samples can be analysed as pressed powder pellets, bulk powder samples, fused pellets or as pills (diluted with a flux, e.g. Spectromelt). For quantitative analyses a flat and homogenous sample surface is needed. Powder samples have to be pulverized to a fineness, where absorption in single grains can be neglected. Solid and liquid samples can be prepared either by thin film techniques, or as samples of infinite thickness. In thin film techniques the amount of sample in the irradiated spot has to be known.

This can be established by adding an internal standard. A specimen can be regarded to be of infinite thickness if

$$D_{\infty} \geq 3 \cdot d_{1/2_{\text{prim}}} \text{ with } d_{1/2_{\text{prim}}} = \frac{\ln 2}{\mu(E_{\text{prim}})}$$

where $d_{1/2}$ = half absorption thickness and μ = mass attenuation coefficient.

Matrix Correction Methods

Thin specimens show a strictly linear dependency of the intensity of a characteristic line on the amount of the analyte. In thick specimens, primary radiation is absorbed along its path in the sample and secondary radiation on its way out. Additionally, secondary excitation by intense characteristic lines with energies above the absorption edge of the analyte can occur. These intensity variations (up to a factor of ~ 20) are strongly matrix dependent and have to be corrected. Different methods can be used.

Normalization of the Compton peak can be applied, if no absorption edge occurs between the Compton peak and the line of the analyte.

$$c_i = (a_i I_i + b_i) \frac{I_{C_{\text{ref}}}}{I_{C_{\text{sample}}}}$$

Empirical, semiempirical and theoretical matrix correction models are used for the determination of major components, where line intensities are influenced by absorption edges and enhancement. Routinely applied is the fundamental parameters model based on theoretically or experimentally determined α -coefficients:

$$c_i = [D + E \cdot I(\lambda_i)] \times [1 + \Sigma(c_j \cdot \alpha_{ij})]$$

or empirical corrections such as

$$c_i = (b_{0i} + b_{1i} I_i + b_{2i} I_i^2 + I_i \Sigma m'_{ij} \cdot I_j + \Sigma m''_{ij} \cdot I_j)$$

or under consideration of elemental concentrations

$$c_i = [b_{0i} + b_{1i}(I_F)_i + b_{2i}(I_F)_i^2] \times \left(1 + \Sigma k'_{ij} \cdot c_j + \frac{\Sigma k''_{ij} \cdot c_j}{1 + c_j} \right)$$

where I_F = fluorescence intensity.

Recent Trends

All modern X-ray fluorescence systems are computer controlled and equipped with automatic sample changers. Different matrix correction models are included in the data evaluation software, and further developments on expert systems will reduce manual calibration work. With WDXRF, the detectability of light elements (down to Be)

will be optimized, e.g. by using X-ray tubes and detectors with ultrathin windows and widely spaced (focusing) analyser crystals. In EDXRF, trends are for miniaturization, development and optimization of high-resolution room temperature detectors and extension of the application range towards the determination of light elements.

Introduction

X-ray fluorescence spectroscopy (XRF) has been applied since the 1970s as a versatile tool to many analytical problems. The analysis of major, minor and trace elements in various kinds of samples can be performed qualitatively as well as quantitatively. The working principle is based on the excitation of the sample atoms by high-energy X-rays, followed by the emission of characteristic photons with a certain energy, well correlated to the atomic number Z of each element (Moseley's law). The determination of the energy (or wavelength) of the emitted photon allows qualitative analysis and the determination of the number of emitted characteristic photons allows quantitative analysis. The fundamental physical principle of X-ray fluorescence is described in the article about the theory of X-ray fluorescence spectroscopy. One of the features of XRF, besides the accurate, rapid, multielement capacity, is that the analysis can be performed nondestructively. In fact, one has to consider that XRF is a surface-sensitive method, because of the energy of the excited and emitted radiation which is in the range 1–115 keV (Na to U K-radiation). The penetration depth of the primary radiation is some μm or so for low- Z elements and some 100 μm or so for heavy elements, depending also on the matrix or type of sample (solid, liquid and powder samples are common). In any case the surface of the object of investigation has to be representative of the entire volume, and thus requires a homogenous sample. Therefore, because of the sample preparation, the 'non-destructiveness' is lost. To perform XRF a spectrometer is required that consists of an excitation source, sample and a detection system, which can be either wavelength-dispersive or energy-dispersive.

The excitation is mostly performed by X-rays produced in and emitted by an X-ray tube. The spectral distribution of the emitted radiation is partly the bremsstrahlung, with a maximum energy corresponding to the applied voltage, and is partly superimposed by the characteristic lines of the respective anode material. The intensity of the emitted radiation depends on the atomic number of the target and the applied voltage. The intensity of the measured fluorescence signal depends on the intensity and energy of exciting photons hitting the sample atoms. Low-power X-ray tubes operating in the few W range and standard X-ray tubes dissipating up to 3 kW, as well as X-ray tubes with a rotating anode, up to 18 kW, are in use. Photons from radioisotopes are used for special applications, offering an excitation source independent of any power supply. The brightest excitation source is synchrotron radiation. It is emitted when bunches of electrons or positrons with energies in the GeV range are travelling along curved sections in a storage ring. An intensive continuous spectrum with a strong natural collimation in the forward direction is emitted. The radiation is continuous from the eV region to some hundreds of keV and linear polarized in the orbital plane.

Due to the different working principles of wavelength-dispersive (WD) and energy-dispersive (ED) XRF the applications differ strongly and it is necessary to work out the special techniques and their advantages and disadvantages.

Instrumentation and Methodology

Wavelength-Dispersive Spectrometers

Two types of WD instruments are in use, the sequential spectrometer and the simultaneous spectrometer. The sequential spectrometer scans the radiation emitted by the sample by changing the angle sequentially. For different wavelength regions different analyser crystals must be used to fulfil Bragg's equation. A set of 6 to 8 crystals with various lattice spacings d is properly mounted and can be changed automatically. The simultaneous spectrometers consist of various combinations of analyser crystals and detectors, arranged around the sample at fixed angle settings. So each 'channel' is optimized to detect an individual wavelength corresponding to an

element. Mostly these channels use focusing optics at the detector to increase the signal. These spectrometers are called simultaneous multielement spectrometers, but the number of simultaneously detected elements depends on the number of channels of the spectrometer. LiF, topaz and other natural crystals are used for the medium-Z elements. The use of synthetic multilayer structures (consisting of alternating layers of a high-Z and a low-Z material with a bilayer thickness of $\sim 1\text{--}10\text{ nm}$) as dispersive elements and measurement in an evacuated environment allows the efficient determination of low-energy characteristic radiation down to even Be-K lines ($\lambda = 11\text{ nm}$) if a flow counter with an ultrathin entrance window is used. The big advantage of the WD spectrometers is their excellent wavelength-to-energy resolution, especially in the low-energy region and the high count-rate range (10^6 cps) in operation.

Energy-Dispersive Spectrometers

An ED detector consists of a semiconductor crystal (Si, Ge) prepared as p-i-n diode, mounted under vacuum, generally operated at 77 K and cooled with liquid nitrogen (LN) and the necessary connected electronics. Therefore a large, heavy dewar (7–30 L of LN) is required for an ED detector. LN consumption is $\sim 1\text{ L}$ a day. The crystal environment has to be a vacuum, and as an entrance window in front of the crystal generally Be is used. Be is chosen as it is available with 8–25 μm thickness, it is vacuum and light-tight and its absorption of low-energy photons is tolerable. If very low energy photons ($E < 1\text{ keV}$) are to be measured, an ultrathin ($< 1\text{ }\mu\text{m}$) entrance window is required. Generally, the energy resolution is much larger with ED detectors than with WD systems, so ED is more susceptible to line overlaps. Especially in the low-energy regions this leads to difficulties in the interpretation of the measured spectrum and mathematical procedures for spectrum deconvolution are required. To overcome the problem of LN cooling, Peltier cooled detectors are available offering smaller size and lighter weight, but worse resolution. As common practice the value for the energy resolution is given at 5.9 keV and is in the range 130–180 eV for LN-cooled detectors, and 175–200 eV for Peltier cooled detectors.

ED spectrometers measure all photons coming from the sample simultaneously. On one hand this is an advantage, because many elements can be detected within a short time, but on the other hand it is a disadvantage, because the maximum count-rate is limited to 50–80 kcps. The processing of the measured signal from each photon requires a certain length of time and during that interval the system is not ready to process the signal from the next arriving photon. The result is a deadtime, which has to be corrected. The reason for the saturation is not the number

of fluorescence photons from the sample mainly, but the exciting radiation being scattered by the sample and the sample carrier. Therefore special techniques have been developed to reduce the scattered radiation.

Use of Monochromatic Radiation

The scattering can be drastically reduced, if monoenergetic radiation is used for excitation. Then only monoenergetic photons are arriving at the sample and can be scattered and so contribute to spectral background. Various methods of producing monoenergetic radiation are in use.

Filtered radiation

The easiest way to reduce the number of photons not used for sample excitation is the insertion of a filter. It mainly absorbs the low-energy bremsstrahlung, but also a filter with Z as $Z_{\text{anode}} - 1$ can be used to effectively reduce the characteristic K_{β} radiation from the anode.

Secondary target excitation

The radiation from an X-ray tube is used to excite a suitable target and the fluorescence radiation from the secondary target is used to excite the sample. This method of achieving quasi-monochromatic radiation suffers from a tremendous loss of photon flux, but this can be compensated for by using higher current from high-power tubes.

Radioisotope excitation (RIXRF)

A few radioisotope sources (with acceptable half-life) emit radiation in the X-ray region, such as Am-241 (59.5 keV), Cd-109 (Ag-K lines, 22 and 25 keV) and Fe-55 (Mn lines, 5.9 keV), and can be used for excitation. The advantage of radioisotope sources is their independence of a generator and power supply, which makes their use interesting for portable instruments, in field, on-line and even extraterrestrial applications. The disadvantage is the low photon flux in comparison to tube excitation.

Crystal monochromators and multilayer structures

Crystal monochromators in the beam path of an X-ray tube allow the selection of either the characteristic line from the anode or the selection of an energy from the continuous spectrum. Monochromators with a high reflectivity as well as a large energy band width are usually preferred, because the product of these two parameters determines the photon flux on the sample. In comparison to crystal monochromators, the multilayer offers high reflectivity as well as larger band width ($dE/E = 10^{-2}$). Higher photon fluxes could be obtained. They are used with either X-ray tubes or synchrotron radiation.

XRF Using a Linear Polarized Beam

If linear polarized radiation is scattered, in the ideal case no scattering radiation is emitted in the direction of the polarization vector. This effect can be used to reduce the scattering from the sample itself. Barkla polarizers or Bragg polarizers can be used. The Barkla polarizer scatters the entire spectrum of the exciting radiation; the Bragg polarizer acts additionally as a monochromator. Both polarizers use the scattering of the unpolarized radiation through an angle of 90° . Using polarized radiation the spectral background is drastically reduced in comparison to nonpolarized radiation, but again losses in intensity occur.

Total Reflection X-Ray Fluorescence Analysis (TXRF)

TXRF is an EDXRF technique, utilizing the total external reflection of X-rays on the smooth plane surface of a reflector material, e.g. polished quartz. If a low divergent beam impinges on the reflector surface at an angle smaller than the critical angle for total reflection, most of the beam is reflected from the surface; only a small part penetrates into the reflector, causing scattered radiation. This leads to a reduced spectral background. The fluorescence signal is enhanced because the primary and also the reflected beam excite the sample, which is deposited on the reflector. Due to the small incidence angle the detector can be brought very close to the sample, so the detection efficiency is high. All these features lead to detection limits in the range of pg. Generally the samples have to be in liquid form. A droplet of 2–100 μL is pipetted onto the sample reflector and the liquid matrix is evaporated. Also, thin films or thin layers, as well as atoms implanted in a reflecting material such as Si-wafers, can be measured and thickness and depths determined.

Microfluorescence Analysis (MXRF)

Microfluorescence analysis indicates the analysed area to be very small, leading to spatially resolved information of the sample composition. There are several methods of obtaining a beam with a small diameter, from a simple pinhole to highly sophisticated X-ray optical elements with focusing characteristics. One very effective method is the use of capillaries using the principle of total reflection of X-rays on the inner walls of a glass capillary. Small diameters down to 1 μm can be obtained with satisfactory intensity.

Synchrotron Radiation-Induced XRF (SRXRF)

Synchrotron radiation, as described above, offers several advantages for use as an excitation source for XRF, especially the higher intensity, orders of magnitude greater

than that offered by an X-ray tube. In combination with a monochromator the exciting radiation can be tuned to the energy with the optimum value of the photoelectric cross section for the investigated sample. It is also possible to tune the energy below the absorption edge of a main element in the sample to excite an element at trace levels with $Z < Z_{\text{main element}}$. This method is called *selective excitation* and offers several advantages in trace element analysis. To perform microanalysis, focusing elements are inserted to produce high-intensity microbeams. Also TXRF can be done using SR as exciting radiation.

Figure 1 Overview of sample preparation techniques typical for XRF.

Trace Element Analysis

To detect elements at trace levels – $\mu\text{g g}^{-1}$ (ppm), ng g^{-1} (ppb) or even pg g^{-1} (ppt) – with XRF, generally special techniques as well as special sample preparation methods have to be used. The relevant quantity for trace element analysis is the limit of detection (DL), which is given by the formula

$$\text{DL} = \frac{3 \cdot \sqrt{I_B/t}}{S}$$

where I_B is the background intensity, t the measuring time and S the sensitivity (cps ppm^{-1} or cps ng^{-1}). Either increasing the sensitivity or reducing the background leads to a reduction of detection limits. Therefore, special techniques of XRF, mainly EDXRF techniques, are applied, like TXRF, MXRF or SRXRF, as methods for trace element analysis. Detection limits range from ng to fg or $\mu\text{g g}^{-1}$ to pg g^{-1} .

Applications

The applicability of XRF is almost unlimited with respect to type of sample and concentration range, but depends very much on the chosen technique. It can be used for on-line analysis in production processes or in-field measurements of geological samples with portable instruments, or quality control, such as impurity determination on Si-wafer surfaces at ultra-trace levels, and environmental investigations. Also sample preparation is an important factor influencing the applicability (see Figure 1). For fine art object investigation or precious objects from museums, absolute nondestructiveness is required, contrary to environmental sampling where homogenizing and pressing to a pellet is no problem.

To describe the various fields of application in detail they are divided into categories.

Metals and Alloys

Process control in today's highly automated production facilities is strongly dependent upon fast, precise and accurate chemical analysis, and XRF has been found to be widely applicable in the metal industries. XRF of metallic samples includes several solvable problems, especially in the areas of sample preparation and modelling calculations to convert intensities into concentration data. In general, metallic samples do not need complicated sample preparation, but the analytical information is derived from a volume close to the surface which must be polished. XRF is applied to various kinds of alloys, such as Na–Mg alloys, and Al, Ti, ferrous, Ni, Cu, Zr, W and Au alloys, bronzes and brass. Typically, simultaneous WD spectrometers with an automatic sample changer are used.

Mining and Ore Processing

In mining and ore processing XRF is used for quality and process control. The spectrometers used differ very much depending on their application. Laboratory spectrometers for quality control may be WD or ED systems with tube excitation. On-stream spectrometers located at in-plant locations, can be WD and ED systems, with radioisotope excitation or X-ray tube excitation and equipped with flow cells. In-stream instruments can be installed in slurry streams, mainly equipped with radioisotope excitation and scintillation counters for single-element determination. Field instruments must be portable and battery operated. The big advantage of XRF over other analytical tools for that application is its simplicity and speed. The usefulness of X-ray instruments to selective mining is well established, the information being used for ore–waste sorting.

Cement Analysis

Finishing cements and raw mixes typically contain Ca, Si, Al and O at high concentrations, plus Fe, K, Mg and Na at low concentrations. One of the major problems in accurate cement analysis is homogeneity, particularly in the case of raw mixes, where the source of raw material may be variable. Most of the elements to be determined are of low atomic number, hence the penetration of their characteristic lines will be of the order of a few micrometres only. Careful grinding and pelletizing will suffice, but the fusion bead technique with Li_3BO_4 is strongly recommended. Simultaneous multichannel WD systems are ideally suited for this kind of application.

Lubricating Oil Analysis

Raw or used oils are usually analysed for additive-element content including Ba, Zn, Mn, Ca, P and Cl, plus naturally occurring elements including S, N, Ni and Na. In blended stocks the concentration of these elements would typically lie in the range 0.01–2.5%. In a standard case the analysis will be performed in the liquid phase and under a He atmosphere. Large matrix effects are likely because of the variable concentration levels of relatively heavy elements in a very low average atomic number matrix.

Geology

XRF offers a rapid, accurate, low-cost method of analysis. Fully automated XRF spectrometers, sequential as well as simultaneous WD instruments, and ED instruments are in use. The analysis of geochemical samples often involves the analysis of samples having concentrations ranging from 0.0001 to 80%. Elements from Na to U are routinely determined. Detection limits depend very much on sample preparation and are in the range $20\text{--}1000 \mu\text{g g}^{-1}$.

for low-*Z* elements, 5–10 $\mu\text{g g}^{-1}$ for medium-*Z* elements and 1–20 $\mu\text{g g}^{-1}$ for high-*Z* elements.

One spectacular application of EDXRF was the Mars Pathfinder which was designed to inspect the rocks on the surface of Mars. Radioisotope excitation was used and one of the new electrically cooled ED detectors mounted on a small vehicle. Surface analysis of rocks could be performed quickly and the data could be transferred to Earth.

Fine Art and Archaeological Objects

In principle, with EDXRF, nondestructive analysis can be performed, which opens up the wide field of art and museum objects. Coins, bronzes, paintings, pottery, ceramics and ancient glasses can all be analysed. Paintings can be analysed pixel by pixel. With a spectrometer mounted on an *x-y* stage, a selected area can be analysed and the whole painting can be scanned. In particular, MXRF techniques are very well adapted to analysing specific points on figures or vessels, as well as lines on ancient documents.

Environmental Analysis

This is probably the most versatile and important application as all kinds of biological material such as plants, roots, needles, food-stuff, algae and lichens as biomonitors can be analysed with XRF. Lichens offer the advantage of a natural sampler collecting aerosols without exchange with the substrate. See Figure 2 as example of a sample lichen measured with an EDXRF spectrometer. Soil, river sediments, sewage sludge, dust, coal fly ash, car exhaust and fog condensate or the aerosols, sampled in impactor stages, are well suited for XRF. All kinds of liquids can be analysed: river water, sea water, snow, ice. However, special techniques for sample preparation

should be applied especially when trace element analysis is required.

Microfluorescence Analysis

MXRF allows spatial resolution of analysis. To perform it with sufficient intensity in the laboratory with X-ray tubes, special optics should be applied such as capillaries. Using capillaries, X-ray tube excitation with SR allows much higher intensities, and so lower detection limits can be obtained. Applications range from microelectronics and plating thickness, maps of bone cross sections, superconductor films, human hair, pig heart muscles, metal alloys, leaves, chinaware, environmental particles, tree rings and glass fragments.

Medicine

In vivo measurements as well as *in situ* measurements and analysis of malignant cells, as well as tissue sampling have been performed. *In vivo* measurements started with the determination of iodine in the thyroid and range from Cd in liver and kidney and Pt in kidneys and tumours, to Hg in the wrists and skulls of dentists, Pb in various near-surface bones, Cu in the eye and Fe in the skin. For the *in vivo* measurements, the use of polarized radiation offers big advantages. Hg and Pb can be analysed by their K-radiation, thus giving information from even deeper tissues. Also, the analysis of biopsy samples, whole blood and blood serum can be performed using EDXRF. Trace element content in malignant and benign tissues was investigated, as well as lung tissue from different factory workers, showing different elements at higher concentrations corresponding to their profession. Various body fluids were analysed, and correlation between trace element content and diseases found. EDXRF, TXRF and SRXRF were used, depending on the task.

Figure 2 An XRF spectrum of a lichen sample. Pressed pellet, measured with a standard EDXRF spectrometer, Rh tube 30 kV, 0.2 mA, 500 s, Pd filter, Si(Li) detector; concentration values of respective elements given in $\mu\text{g g}^{-1}$.

TXRF Applications

TXRF extends EDXRF to a method for trace and ultratrace element analysis. A special feature is the small sample amount required, which is in the range μg – ng of a solid material and less than 100–10 μL of a liquid. Therefore, TXRF is a microanalysis method and samples can seldom be analysed as-received. Pretreatment is generally required to prepare the samples as solutions, suspensions, fine powders or thin sections. For a determination of ultratraces, the matrix of the sample should be separated and removed. All preparation techniques can be applied that have been tested with other methods of atomic spectrometry, e.g. AAS, inductively coupled plasma mass spectrometry. The quantification is generally very simple, because the sample forms a thin layer, so the thin-film approximation is valid. One element of known concentration has to be added as

Table 1 Influence of sample preparation on detection limits in TXRF (after Klockenkämper R (1997))

Sample	Drying	Freeze-drying	Chemical matrix separation	Open digestion	Ashing	Suspension	Solution	Pressure digestion	Freeze cutting
Rain, river water	0.1–3 ng mL ⁻¹	20–100 pg mL ⁻¹	3–20 pg mL ⁻¹	1–3 ng mL ⁻¹	40–220 ng mL ⁻¹				
Blood, serum			Digest: 2–30 ng mL ⁻¹	20–80 ng mL ⁻¹					
Air dust, ash, aerosols				5–200 µg g ⁻¹		10–100 µg g ⁻¹	0.1–3 µg g ⁻¹		
Air dust on filter								0.2–6 ng cm ⁻²	
Suspended matter				3–25 µg g ⁻¹	0.6–20 ng cm ⁻²	10–100 µg g ⁻¹			
Sediment						10–100 µg g ⁻¹		15–300 µg g ⁻¹	
Powdered biomaterial						1–10 µg g ⁻¹		0.2–2 µg g ⁻¹

internal standard. Quantification can be performed after the determination of the sensitivity factors of all elements relative to the internal standard. Also, surface and thin-layer analysis, as well as analysis of atoms below a reflecting surface, can be performed by varying the angle of incidence in the region of total reflection. This angle-dependent intensity profile allows a qualitative differentiation between contaminations on the surface, in the layers, in implantations or in so-called residues after evaporation of liquid samples. Quantitative determinations can be made by applying an algorithm deduced from theory in combination with an external standard.

It is obvious that the sample preparation technique used influences the detection limits. **Table 1** shows this influence on various samples from different fields of application. **Table 2** gives an overview of applications of TXRF already analysed. **Figure 3** shows a spectrum of a water standard reference sample (NIST 1643c) obtained with a TXRF vacuum chamber, constructed at Atominstitut, Vienna. Generally, an excellent field of application of TXRF in trace element analysis can be seen in liquid samples. All kinds of liquids, ranging from different kinds of water to acids and oils, as well as body fluids, can be analysed. Environmental samples, like airborne particles, plant material or medical and biological samples such as tissue, can be analysed directly on a reflector.

The main industrial application of TXRF is the surface quality control of Si-wafer material. Wafers offer the required flatness and are polished, so that they can be directly analysed by TXRF. Several commercial instruments have been developed as wafer analysers and many instruments are utilized in the semiconductor industry. TXRF is capable of checking the contaminations brought in by different steps during the production process. The required sensitivity is now 10^9 atoms cm^{-2} for transition elements like Cr, Fe, Co, Ni, Cu and Zn. TXRF has an 'up-time' of 90% and is nondestructive. Surface mapping can be performed and differentiation between film type or particle type is possible. The detection limits can be improved by more than two orders of magnitude, if the impurities of the entire surface of the wafer are collected and preconcentrated prior to TXRF analysis. The native oxide layer is dissolved by HF vapour and the impurities remaining on the surface are collected by scanning the wafer with a drop of a suitable liquid. This method has the advantage of higher sensitivity, but nondestructiveness is lost.

It is also possible to measure the thickness of near-surface layers in the range 1–500 nm on reflecting substrates with TXRF. Single layers as well as multilayer samples can be analysed. Also, atoms implanted in the reflecting surface can be detected. The implantation depth as well as the depth profile can be determined.

TXRF can also be applied to fine art and museum objects. The sampling technique – a dry cotton bud can

Textile fibres, glass, cognac, dollar bills, gunshot residue, drugs, tapes, sperm, fingerprints.	

be used to rub off a small amount of paint – can only be applied during restoration, because the varnish has to be removed. For analysis the bud is dipped onto a sample carrier by a single tip. An amount of less than 100 ng is transmitted and can be analysed.

Application of SRXRF

The rapid development of the SR X-ray sources since about 1975 is having an impact on X-ray analysis. Due to the features of SR, especially the small source size and therefore the high brilliance, the use of microprobes is obvious. There are several approaches to producing a microbeam; the simplest is to use a pinhole collimator,

Figure 3 Spectrum of water sample, NIST 1643c standard reference material, 10 μL , dried on a quartz reflector, measured with the TXRF vacuum chamber of Atominstut, Mo monochromatic excitation, 40 kV, 50 mA, 1000 s; concentration values of respective elements given in $\mu\text{g L}^{-1}$.

but more sophisticated systems use focusing optics. Monochromatic as well as continuous radiation is used. Because SR is linearly polarized in the orbital plane, scattering from the sample is reduced, leading to low detection limits. SRXRF is a trace element analytical method as well as an MXRF method. SRXRF is performed at several SR facilities, most prominently NSLS Brookhaven, HASYLAB Hamburg, SSRL Stanford, SLS Daresbury, Photon Factory Tsukuba, DCI Lure and ESRF Grenoble. The available spot sizes are in the region of 10 μm and the detection limits in the low pg to fg range. Interesting applications are found in the fields of geology (mineral inclusions can be analysed), as well as in biology and medicine (distribution of trace elements in bone, tooth, brain, hair or algae strands, tree rings and aerosol particles), giving interesting information. Also, application in archaeology is found, letters in different ancient papers being analysed to allow the differentiation of the ink used to help identify the workshop. Even extraterrestrial minerals and rocks have been analysed.

TXRF can also be done using SR as the excitation source (SR-TXRF) offering the advantage of higher photon flux and improved detection limits. Experiments are performed at SSRL, HASYLAB, Photon Factory and ESRF. The main application is the surface quality control of Si-wafers. With SR-TXRF, detection limits on wafer surfaces of 10^7 atoms cm^{-2} have been obtained. At SSRL there is a beamline dedicated for routine wafer analysis. SR is the ideal source for the excitation of low-Z elements. It offers high intensity also in the low-energy

region, in comparison to standard X-ray tubes. They do not emit enough intensity in the low-energy region; therefore the analysis of low-Z elements always lacks intensity of the fluorescence lines. TXRF is also applied to the determination of low-Z elements using a special detector. Detection limits of 60 fg for Mg have been achieved using SR and have to be compared to 7 pg with windowless Si-anode tube (prototype) excitation.

SR-TXRF generally is a very fast growing field and the problem of reduced access to SR sources for routine analytical applications is becoming less severe due to the large number of dedicated facilities.

Table 3 gives an overview of applications and techniques for an illustrative 5 year time window.

Conclusions

Applications range from on-line analysis and in-field inspections to ultratrace analysis of semiconductor surfaces. There is almost no sample that cannot be analysed by XRF as long as elemental analysis is required. The achievable detection limits depend on the method used and range from $\mu\text{g g}^{-1}$ (ppm) to pg g^{-1} (ppt). Non-destructive analysis can be performed but sometimes sophisticated sample preparation techniques are required. The elemental range (Be to U) depends on the excitation source as well as the detection system. Generally XRF can be seen as a workhorse for elemental analysis and is easy to use.

X-ray is the region of the electromagnetic spectrum lying between gamma rays and extreme ultraviolet (XUV/EUV) corresponding to a wavelength range of about 0.1 to 100 Å. The radiation on the lower end of the XUV region, up to about 300 Å, is also sometimes referred to as X-ray. On the lower wavelength side, radiation of shorter wavelengths is termed X-ray if it is nonnuclear in origin. The wavelength of the radiation is related to the photon energy by the

standard relation $E \text{ (keV)} = 12.4/\lambda \text{ (Å)}$. In terms of energy, the X-ray region is roughly between 125 eV and 125 keV. Being electromagnetic radiation, X-rays can be reflected, refracted, scattered, absorbed, polarized, etc. They also show interference and diffraction effects.

There are several sources of X-rays such as a Coolidge tube, vacuum sparks, hot-dense fusion plasmas, synchrotron, pinch devices, muonic atoms, beam-foil interaction, stellar X-ray emitters, solar flares, etc. The X-rays originating from all these sources can be broadly categorized into three main types: (1) atomic inner shell transitions, (2) emission by free electrons, (3) X-rays from few electron systems. The basic spectroscopic aspects of the various types of X-rays are discussed in this article.

X-Rays from Inner Shell Transitions in Atoms

X-rays are produced when an electron in an outer shell of an atom jumps to an inner shell to fill an electron vacancy. The difference in energy is emitted as an X-ray photon. The vacancy giving rise to such a transition can be produced by an energetic photon, bombardment of charged particles (e^- , p , $\alpha\ldots$), or by nuclear processes such as internal conversion, K-capture, etc. If a charged particle collision or a nuclear process produces the vacancy, the resulting X-ray emission is called primary. If the vacancy is produced by an X-ray photon, the subsequent emission is called secondary or fluorescence radiation.

In all these cases the singly ionized atom lowers its energy by emission of a photon of definite wavelength which is characteristic of the emitting atom. Hence, these X-rays are also called characteristic X-rays.

Characteristic X-Rays

The most energetic X-ray emission comes when a vacancy in a K shell ($n=1$) is filled by an outer electron. Removal of a 1s electron from a neutral atom raises it to the highest energy state represented by $1s1s^{-1}$ or $1^2S_{1/2}$ or K_I . Removal of a 2s electron ($2s2s^{-1}$) gives rise to L_I state ($2^2S_{1/2}$). Removal of a 2p electron from a filled 2p shell ($2p^5p^{-1}$) gives rise to $L_{II}(2^2P_{1/2})$ and $L_{III}(2^2P_{3/2})$ states, respectively. Similarly, removal of a 3s, 3p, 3d electron from filled shells gives rise to $(3s3s^{-1}, 3p^5p^{-1}, 3d^9d^{-1}) M_I(3^2S_{1/2}), M_{II}(3^2P_{1/2}), M_{III}(3^2P_{3/2}), M_{IV}(3^2D_{3/2}), M_V(3^2D_{5/2})$ states.

The selection rules applicable to optical dipole transitions also apply to X-ray transitions. The rules are $\Delta L = \pm 1$, $\Delta j = 0, \pm 1$. Intensity rules are also the same as those applicable to optical transitions. The transitions obeying selection rules are called normal transitions. Not all transitions allowed by selection rules are observed. On the contrary, some transitions, which are not allowed by selection rules, are sometimes observed. These are called forbidden transitions. The observed lines were initially given names as per their observed line intensities. The Siegbahn notation used to name various observed lines is given in **Table 1**. As this nomenclature is intensity-based (e.g. K_{α1} more intense than K_{α2}) and was adopted long before the origin of the lines was explained spectroscopically, this notation is somewhat confusing.

Moseley's law gives the frequency of line transition as $\nu(\text{cm}^{-1}) = KR(Z - \delta)^2$, where R is the Rydberg constant, and Z is the atomic number. For example, for K_α: $\delta = 1$ and $K = 3/4$, which gives $\nu(\text{cm}^{-1}) = (3/4)R(Z - 1)^2$. Similarly, for L_{β1}, $\nu(\text{cm}^{-1}) = (1/2^2 - 1/3^2) R(Z - 7.4)^2$.

The energy levels formed by single electron removal are similar to those of a hydrogen-like atom, obtained by replacing Z by $(Z - \sigma)$ and $(Z - s)$ in the Sommerfeld

formula, where σ and s are screening constants. The energy of a level is given by the modified Sommerfeld formula as

$$T = R(Z - \sigma)^2/n^2 + R\alpha^2(Z - s)^4 \\ (n/k - 3/4)/n^4 + O(\alpha^4, \alpha^6, \dots)$$

where α is the fine structure constant, n is the total (principal) quantum number, and k is the Sommerfeld original azimuthal quantum number; $k = 1, 2$ and 3 for s, p and d electrons, respectively.

A pair of terms having the same n, s, L but different j (in the $^{2s+1}L_j$ Russel-Saunders notation) is called a spin-relativity doublet (earlier called a regular doublet). L_{II}–L_{III}, M_{II}–M_{III}, M_{IV}–M_V are examples of such doublets. The screening constant σ (same for a doublet) depends on s, p, d sub-levels but s is the same for a spin-relativity doublet, almost independent of Z (s values: L_I: 2.0, L_{II}–L_{III}: 3.5, M_I: 6.8, M_{II}–M_{III}: 8.5, M_{IV}–M_V: 13).

A pair of terms having the same n, s and j but different L values is called as screening doublet (or irregular doublet). L_I–L_{II}, M_I–M_{II}, M_{III}–M_{IV} are examples of such screening doublets.

From the first term of the Sommerfeld formula, one obtains the screening doublet law, which states that the difference between the square roots of the term values of a given doublet is constant, i.e. independent of Z . This term also gives the irregular doublet law which states that the difference between term values of an irregular (screening) doublet is a linear function of Z .

The second term of the Sommerfeld formula gives the separation in energy for a spin-relativity doublet as proportional to the fourth power of the screened atomic number, i.e. $(Z-s)^4$. This is referred to as the regular doublet law. For example, for the $L_{II}-L_{III}$ doublet (same σ), $\Delta\nu(\text{cm}^{-1}) = (R\alpha^2/16)(Z-3.5)^4$.

Satellite Lines

These are weaker lines appearing on the shorter wavelength side of the normal (characteristic) lines. They were initially referred to as nondiagram lines because unlike the normal lines, these lines did not fit conveniently in the energy level diagrams of that time. Later, it was realized that the energies can also be predicted using energy level diagrams of multiply charged ions (Figure 1).

The satellite lines are due to additional electron vacancy in a doubly ionized atom. Due to the absence of a second electron, the energy levels shift to the higher energy side (relative to those of a singly ionized atom) due to reduced Coulomb screening. As a result, single electron transitions in such atoms (doubly ionized) are at a slightly higher energy compared to those in singly ionized atoms. As the probability of creation of two electron vacancies in an atom

is much smaller than that of a single vacancy, the intensity of satellite lines is much less than that of normal lines.

Satellite lines are denoted as α' , α'' , α''' where the higher number of primes implies lower intensity. If $K-M$ (i.e. $K_{II}-M_{III}$, M_{III}) denotes a K_{β} transition, then $KL-LM$ denotes the satellite line K_{β}''' which is due to an additional vacancy in the L shell (Figure 1).

Hypersatellite lines

This is a special case of satellite lines wherein X-rays originate from atoms with two holes in the same inner shell. A K-hypersatellite line appears when an atom has initially two vacancies in its K shell. They are denoted by superscript H. For example, $K_{\alpha 1,2}^H$ is a hypersatellite of the $K_{\alpha 1,2}$ line (Figure 2). Due to the strong reduction of screening, there is a large energy difference between a normal line and its hypersatellite. Hypersatellites are more easily observed in heavy ion collision spectra or radioactive decay by K-electron capture.

Plasma satellites

These are low intensity structures, which can appear on either side of a parent line. They are equally spaced and correspond to an energy difference of $(b/2\pi)\omega_p$, where ω_p is the plasma frequency given by $\omega_p^2 = (N_e e^2 / \epsilon_0 m)$ where N_e is the electron density in the conduction band of the solid target material.

If an X-ray photon loses its energy in exciting a plasmon, one obtains a low energy plasmon satellite. On the other hand, if plasmons already exist in the solid at the time of X-ray emission, they can lead to high energy satellites.

Figure 1 Energy diagrams for a K_{β} transition and K_{β}''' satellite transition. $A()$ denotes the state of an atom. For example, $A(M^+L^*)$ denotes an atomic level where an M shell electron has been removed and an L shell electron is in an outer bound (excited) state. The energy difference $E_{KL} - E_K$ is more than $E_{ML} - E_M$ as more energy is required to remove an L shell electron in the presence of a K shell vacancy than in the presence of an M shell vacancy. Solid downward arrows show vacancy transitions, and dashed lines with double arrows show radiative transitions.

Figure 2 Energy diagram for $K_{\alpha 1,2}^H$ hypersatellite transition.

Auger and Allied Processes

These processes compete with the radiative process in de-excitation of the atom. Thus they influence the energy-width of X-ray lines. Moreover, they transfer a vacancy from one level to another and thereby affect the intensity of X-ray lines. Many of these processes also lead to double ionization which (as discussed earlier) gives rise to satellite lines. Some of these processes are briefly described below.

Auger ionization

In this case, an inner shell vacancy is filled by an electron from an outer shell and the excess energy, instead of being emitted as a photon, is consumed in ejecting a second electron (called an Auger electron) from the atom. This is a radiationless process leading to double ionization. A transition of an electron from an L shell to a K shell vacancy, accompanied by the ejection of an L shell electron, is represented as a KLL transition. The energy of the ejected electron in a KLL transition is $E_{\text{Auger}} = E_K - E_{LL}$. Here E_K is the energy of the atom with one electron missing in the K shell and E_{LL} is the energy of the level formed by ejection of an L shell electron from a singly ionized atom with an L shell electron vacancy (Figure 3a).

Radiative Auger process

In this process, the Auger electron, instead of carrying away all the energy, receives only a part of it and the rest is emitted as an X-ray photon. The energy of the photon is given by $h\nu = E_{\text{Auger}} - E_{\text{kin}}$ where E_{Auger} is the energy of the electron in the Auger transition involving the same three levels (e.g. KLL), and E_{kin} is the kinetic energy of the ejected electron. The energy spectrum of the emitted X-rays is continuous,

with a maximum energy $h\nu = E_{\text{Auger}}$, corresponding to zero kinetic energy of the ejected electron (Figure 3b).

Semi-Auger process

If, in the above radiative Auger process, the electron, instead of being ejected out of the atom, is transferred to some outer bound state, then the energy of the emitted X-ray photon would be discrete having the value $(E_K - E_L) - E_b$. Here, E_b is the difference in energy between the outer bound state and the energy level of the electron in an atom with an L shell vacancy (Figure 3c). This process is referred to as a semi-Auger process.

Coster-Kronig process

This is a special case of Auger ionization in which the vacancy transition is between two levels with the same principal quantum number (i.e. within the same shell; $\Delta n = 0$) and an electron from some outer shell (different n) is ejected (e.g. LLM transition: see Figure 4).

Super Coster-Kronig process

This is an Auger transition wherein not only the vacancy transition is within the same shell ($\Delta n = 0$ as in a CK transition), but the electron is ejected from the same shell (e.g. MMM transition: see Figure 5).

Autoionization

This process is similar to Auger ionization. In this case a vacancy is created by promoting an inner shell electron to an outer bound level, instead of being ejected from the atom. When this vacancy is filled by an outer shell electron, if the difference in energy exceeds the ionization potential of any electron, then that electron is ejected leading to a singly ionized atom (Figure 6).

Figure 3 Energy diagrams for: (a) Auger transition, (b) radiative Auger transition, and (c) semi-Auger transition.

Figure 4 Energy diagram for LLM Coster-Kronig transition.

Figure 5 Energy diagram for MMM super Coster-Kronig transition.

Figure 6 Energy diagram for autoionization. An L shell electron is excited to an outer nl shell. Subsequently, an M shell electron fills up the L shell vacancy. In case A, the excited electron in the nl shell leaves the atom, and in case B, another M shell electron leaves the atom while the nl shell electron remains a spectator electron.

The differences between autoionization and Auger ionization are as follows: (a) Autoionization results from an electron vacancy produced by the excitation of a core electron to an outer bound level, whereas Auger ionization results from an electron vacancy created by ejecting a core electron from an atom. (b) Autoionization takes place in a neutral atom leading to a singly ionized atom, whereas Auger ionization takes place in a singly ionized atom leading to a doubly ionized atom.

There is a quite high probability (at least for K shell ionization) of the order of 20%, that the first ionization producing the initial vacancy is simultaneously accompanied by the excitation or emission of a second electron. If the second electron is excited to some bound state, the process is called shake-up. If the second electron is ejected, the process is called shake-off.

The Auger processes compete with radiative decay. The probability of radiative decay is proportional to Z^4 , whereas the probability of Auger ionization is constant, independent of Z . The fluorescence yield (ω) is defined as the ratio of the number of vacancies filled by X-ray emission to the total number of vacancies (filled by all processes). For K shell, $\omega_K = \text{number of K X-ray photons} / (\text{number of K X-ray photon} + \text{number of Auger electrons}) = Z^4 / (Z^4 + \alpha)$, where $\alpha = 1.12 \times 10^6$. Hence, for low Z atoms, the fluorescence yield is low due to strong competition from Auger processes (for $Z < 33$, $\omega_K < 1/2$).

Because satellite lines are due to doubly ionized atoms, and since Auger processes dominate for low Z atoms, satellite lines are more prominent in the spectra of low Z atoms compared to high Z atoms.

X-Ray Emission by Free Electrons

From electromagnetic theory, any accelerating charge will radiate, with the intensity of emission being proportional to

the square of the acceleration. Electrons, due to their smaller mass, undergo higher acceleration for a given force and hence emit more intense radiation. The spectrum of the emitted radiation called Bremsstrahlung (braking radiation) depends on the nature and magnitude of the acceleration. We discuss here three main sources of X-ray based on electron acceleration (deceleration), namely (i) X-ray tubes (linear acceleration, monoenergetic electrons), (ii) hot plasma sources (linear acceleration, Maxwellian distribution of energy) and (iii) synchrotron sources (transverse acceleration). The X-ray spectra from these differ from each other.

X-Ray Tube

In this case, thermionically generated electrons are accelerated by a d.c. (or pulsed) potential (V) to several keV energy and are abruptly slowed down by impinging them on a solid target. Due to this deceleration, Bremsstrahlung radiation is emitted. The maximum emission is in the direction perpendicular to the acceleration. Accordingly, the target surface in an X-ray tube is kept at an angle to the electron beam.

The total intensity of the X-ray emitted is given by $I \propto ZV^2$.

The efficiency of X-ray conversion is given by $\epsilon = \text{X-ray power} / \text{electron beam power}$. Experimentally, the value of ϵ is about $1.1 \times 10^{-9} Z(V + 10.3Z)$ or $\sim 1.1 \times 10^{-9} ZV$ for large accelerating voltage. This means that the X-ray conversion efficiency is better for higher Z targets and at higher accelerating voltages. However, even for a high- Z material like tungsten ($Z = 74$) at a voltage of 50 kV, the efficiency is only about 0.4%. The rest of the e^- beam energy is spent mostly in heating the target. It is therefore necessary to have an X-ray tube anode with a high melting point in either a rotating or cooled (or both) configuration to prevent it from melting.

Figure 7 Bremsstrahlung emission spectrum from an X-ray tube.

The X-ray energy distribution for a thin target is given by

$$I_\nu = I_0 \quad \text{for } \nu \leq \nu_{\max} \\ = 0 \quad \text{for } \nu > \nu_{\max}$$

where $h\nu_{\max}$ is the maximum energy of the X-ray photon, equal to the electron beam energy. This corresponds to the case where the electron loses its full energy in a single collision. It is also referred to as the Duane–Hunt limit.

The above spectral distribution is true for a thin target where the electron undergoes a single collision. However, in practice, the target is thick and the electron is scattered (decelerated) many times. As a result, the energy spectrum becomes

$$I_\nu = KZ(\nu_{\max} - \nu) \quad \text{for } \nu \leq \nu_{\max} \\ = 0 \quad \text{for } \nu > \nu_{\max}$$

The spectral distribution, in terms of X-ray wavelength, is given by (Figure 7).

$$I_\lambda = cI_\nu/\lambda^2 \sim Kc^2 Z(\lambda - \lambda_{\min})/\lambda^3 \lambda_{\min} \quad \text{for } \lambda \geq \lambda_{\min} \\ = 0 \quad \text{for } \lambda < \lambda_{\min}$$

Here $\lambda_{\min}(\text{\AA}) = 124\,000/V$. The peak of the X-ray emission is at $\lambda \cong (3/2)\lambda_{\min}$. For example, for an accelerating voltage of 50 kV, $\lambda_{\min} = 0.25 \text{ \AA}$ and the spectral distribution has a peak at $\lambda = 0.37 \text{ \AA}$.

The Bremsstrahlung radiation from a thick target is only partially polarized. However, at wavelengths near

Figure 8 Bremsstrahlung emission spectrum from hot plasma.

$\lambda_{\min}$, the radiation is strongly polarized in the plane containing the X-ray and the electron beam directions.

It may be noted that if the energy of the electron exceeds the binding energy of the inner shells of the target material, the impinging electron can also knock out core electrons from the target atoms, creating inner shell vacancies, leading to emission of characteristic X-rays of the target material. These X-ray lines are superimposed on the continuous Bremsstrahlung spectrum.

Hot Plasma Sources

These include sources such as laser-produced plasmas, tokamak plasmas, pinch plasmas, solar flares, stellar X-ray emitters, etc. In such plasmas, the electron temperature (corresponding to a Maxwellian velocity distribution) can be a few hundreds of eV to several keV. On collision with plasma ions these energetic electrons undergo acceleration/deceleration and thereby emit Bremsstrahlung radiation. Electron–electron collisions do not emit any net radiation as the two colliding electrons undergo exactly equal and opposite accelerations. The radiation emitted by the two electrons is therefore equal in magnitude and opposite in phase. Hence, there is no net radiation emitted.

For a Maxwellian velocity distribution of the electrons in the plasma, the spectral distribution of the emitted Bremsstrahlung radiation is given by (Figure 8)

$$I_\lambda = CN_e \sum_i N_i z_i^2 T_e^{-1/2} g_f \exp(-hc/\lambda kT_e)/\lambda^2$$

where N_e is the electron density, N_i is the ion density of charge i , and z is the average ion charge. The factor g_f is of the order of unity and it represents a departure of quantum mechanical calculations from the classical results. This factor is called the Gaunt factor. The peak of this spectrum is at $\lambda_p(\text{\AA}) = hc/2kT_e \sim 6.2/T_e(\text{keV})$.

The spectral distribution of the X-ray Bremsstrahlung emitted from a hot plasma is shown in **Figure 8**, which shows a strong temperature dependence of the spectrum for $\lambda < \lambda_p$. This fact is often used for estimation of the electron temperature of the plasma.

It may be noted that, unlike the Bremsstrahlung emission from X-ray tubes, there is no short wavelength limit here as the electrons have all possible energies.

Recombination radiation

In addition to Bremsstrahlung radiation, a hot plasma also emits recombination radiation. This radiation is emitted when a free electron is captured in a bound state of an ion. If E is the kinetic energy of a free electron and χ_n is the ionization potential of the energy level in which the electron is captured, the radiation is emitted with a photon energy of $h\nu = E + \chi_n$ (**Figure 9**). As the free electron has a continuous energy distribution, the emitted radiation spectrum is also continuous for $h\nu \geq \chi_n$. Further, since the recombination can occur in different energy levels of the ion, the overall spectrum is quasi-continuous showing discontinuities at energies equal to the ionization potential energies of various levels. The overall shape of the spectrum is similar to that of plasma Bremsstrahlung radiation shown in **Figure 8**.

Interestingly, whereas in an X-ray tube, the radiation is on the longer wavelength side of the Duane–Hunt limit, here the spectrum is on the shorter wavelength side of the ionization potential.

Cyclotron radiation

If the hot plasma happens to be magnetized (like the tokamak/pinch plasma, X-ray binary stars, etc.), then the

Figure 9 Energy diagram for recombination radiation.

electrons also emit cyclotron radiation (also called magnetic Bremsstrahlung) due to their gyration around the magnetic lines of force. The acceleration is due to the Lorentz force acting on the moving electrons.

The radiation spectrum is a discrete line spectrum at an electron cyclotron frequency (ω_c) and its harmonics: $\omega = n\omega_c$, where $\omega_c = eB/m \cong 1.76 \times 10^{11} B$ (T) rad s^{-1} .

Although the spectrum is independent of electron temperature, the total power radiated is proportional to both the electron temperature (T_e) and electron density (N_e) and is given by P_c (W/m^3) $\cong 4.4 \times 10^{-28} N_e$ (m^{-3}) $B(T)^2 T_e$ (eV).

Synchrotron radiation sources

In a synchrotron source, electrons move with relativistic speed ($v \sim c$). Although this speed is almost constant, when the electron trajectory is bent using bending magnets, the electrons undergo transverse acceleration and radiate energy. This radiation is called synchrotron radiation.

The power radiated is given by

$$S = (e^2 c / 6\pi\epsilon_0) \gamma^4 / R^2$$

where $\gamma = E/m_0 c^2$ and R is the radius of the electron trajectory. For an electron beam of energy E (GeV) and a bending magnet field of B (T), the radius of the electron trajectory is given by $R = 3.33 E/B$ m.

Since the motion of the electron is relativistic, the radiation (emitted perpendicular to the direction of acceleration) is highly concentrated in the direction of velocity within a narrow cone of nominal angular width $1/\gamma$.

Since the radiation is emitted in the form of a searchlight-like cone, an observer receives this radiation for a very short time period $\Delta t \sim 4R/3c\gamma^3$. As a result, the emitted radiation has a large bandwidth given by $\Delta\omega = 2\pi/\Delta t = 3\pi c\gamma^3/2R$. Thus the observed radiation is a continuous spectrum over a large frequency range.

The critical frequency is defined as the frequency which divides the synchrotron radiation power spectrum into two equal parts. This frequency is given by $\omega_c = 3c\gamma^3/2R$, and the corresponding critical energy is given by

$$E_c(\text{keV}) = 3hc\gamma^3/4\pi R = 0.665 B(T) E^2(\text{GeV})$$

Also, the critical wavelength is given by

$$\begin{aligned} \lambda_c &= 2\pi c/\omega_c = 4\pi R/3\gamma^2 = 5.6 R(\text{m})/E^2(\text{GeV}) \\ &= 18.6/B(T) E^2(\text{GeV}) \end{aligned}$$

The synchrotron radiation from a bending magnet is linearly polarized when observed in the plane of the e^- orbit. Out of this plane, it is elliptically polarized with opposite helicity on either side of the plane.

Periodic magnetic structure

In order to enhance the X-ray emission from the synchrotron, periodic magnetic structures are sometimes inserted in the linear sections of the synchrotron. This makes the electron motion sinusoidal in a horizontal plane. An important parameter characterizing the electron motion is the deflection parameter (K) given by $K = 93.4 \lambda_u \text{ (m)} B \text{ (T)}$, where λ_u is the period of the magnetic structure.

Undulator

For low magnetic field ($K < 1$) the angular excursion of the electron is within the nominal $1/\gamma$ radiation cone. In this case, the electron beam breaks up into equally spaced bunches and the radiation from these bunches adds coherently (in phase). Such a magnetic structure is called an undulator. The emitted coherent radiation is at harmonics of $\lambda_L = (1 + 0.5 K^2) \lambda_u / 2\gamma^2$. The relative bandwidth of the n th harmonic is given by $\Delta\lambda/\lambda = 1/(nN)$, where N is the number of magnetic periods. Along the axis, only odd harmonics are observed. However, if a helical magnetic structure is used, the radiation will be circularly polarized and there will be no harmonics present in the on-axis radiation. The emission cone is further narrowed down to $\theta \sim 1/(\gamma\sqrt{N})$. The total radiation flux is N^2 times the flux due to a single bending magnet.

If such a structure is placed in an optical resonator or used as an amplifier for radiation of wavelength $\lambda = \lambda_L$, then it is referred to as a free electron laser.

Wiggler

If the electron excursion angle exceeds $1/\gamma$ (i.e. when $K \gg 1$) then the magnetic structure is called a wiggler. Here, the radiation from different sections of the electron trajectory (where the direction of electron motion makes an angle less than $1/\gamma$ with the axis) adds up incoherently. The total radiation flux is $2N$ times the flux due to a single bending magnet. The emission cone is several times larger than that of the synchrotron radiation.

The total power emitted by an undulator or wiggler is given by

$$P(\text{kW}) = 0.633 E^2(\text{GeV}) B^2(\text{T}) L(\text{m}) I(\text{A})$$

where L is the total length ($= \lambda_u N$) of the magnetic structure, and I is the beam current.

For a planar magnetic field in the vertical direction, the on-axis radiation is polarized in the horizontal plane, as in the case of a bending magnet. However, unlike the bending magnet case, for a periodic magnetic structure, the off-axis radiation is also plane-polarized in the horizontal plane. This is because the vertical component of polarization emitted in one half is cancelled by the radiation in the next half (out of phase) as both have the same direction of polarization. However, the horizontal

polarization in the two halves being opposite in direction, the net radiation adds up.

X-Rays from Few Electron Systems

X-rays from a few electron systems such as hydrogen-like, helium-like, lithium-like ions are observed in hot plasmas (laser produced/tokamak/Z pinch), beam-foil experiments, heavy ion collisions, solar flares, etc. Muonic atoms also emit X-rays.

Ionic X-Rays

Transitions in the highly charged ions are in the X-ray region and are interesting because they are relatively simple to interpret. They are also one of the few cases in atomic physics wherein high order multipole transitions are observed.

Hydrogen-like ions

These are ions having a single electron left. The energy levels of these ions are exactly the same as those of the hydrogen atom except that they are increased by a factor Z^2 , where Z is the atomic number of the ion.

$$E(n, l) = Z^2 E_H(n, l)$$

The hydrogen-like series is composed of transitions of the type $(np)^2 P_{3/2, 1/2} - (1s)^2 S_{1/2}$, where $n \geq 2$. Each line of the series is a doublet. The limit of this series is the highest energy X-ray line that can be emitted by a given element.

Unlike the hydrogen Lyman- α doublet ($\Delta\nu = 0.36 \text{ cm}^{-1}$) which cannot be easily resolved due to Doppler broadening even in moderate temperature ($\sim 10^4 \text{ K}$) plasmas, the fine structure in high Z elements can be easily resolved even in high temperature ($\sim 10^6 \text{ K}$) plasmas. For example, in H-like calcium, the wavelengths of the Ly_α doublet are $3.018 \text{ \AA}$ and $3.24 \text{ \AA}$, which can be easily resolved with a standard crystal spectrometer.

Helium-like ions

These are ions with only K shell electrons left. Here, except for the ground state which is a singlet (1S_0), all the excited levels ($n \geq 2$) have both singlet and triplet states (Figure 10). The helium-like series is composed of transitions of the type $(np \ 1s) \ ^1P_1 - (1s^2) \ ^1S_0$. The end point of the series is the ionization potential of the 1s electron in its $(1s^2) \ ^1S_0$ ground state.

Types of transitions

The terminology for X-ray transitions in ions is the same as that of optical transitions in an atom. The three main types of transitions observed in an ionic line spectrum are: (1) resonance transitions, (2) intercombination transitions, and (3) satellite transitions.

Figure 10 Energy level diagram for helium-like ions showing resonance, intercombination, and other transitions.

Resonance transitions

These are transitions from an excited state to the ground state (**Figure 10**). The H-like series and He-like series discussed earlier are resonance transitions. The oscillator strengths of these transitions are higher than those of other types of transition. For the same reason, these lines can be strongly reabsorbed if they are emitted by a hot-dense plasma. They follow the normal selection rules applicable to optical transitions.

Intercombination transitions

These transitions are similar to resonance transitions except that they are between states of different multiplicity (e.g. triplet to singlet). Corresponding to a resonance transition $(1s2p) \ ^1P_1 - (1s^2) \ ^1S_0$ (which is a singlet-singlet transition), the intercombination transition (triplet-singlet) is $(1s^2p) \ ^3P - (1s^2) \ ^1S_0$ (**Figure 10**). These lines appear on the lower energy side of the resonance lines. Though $^3P_1 - ^1S_0$ is a spin-forbidden transition, in high Z ions, the 3P_1 state decays by dipole transition through mixing with 1P_1 states.

Satellite lines

These are weaker lines arising from doubly excited ions of higher ionization states. The satellite lines of H-like ions are due to He-like ions, those of He-like ions are due to Li-like ions and so on. For example, transitions in Li-like ions of the type $1s\ n'l' \rightarrow 1s^2\ n'l'$ will appear as a satellite to $1s\ nl - 1s^2$ resonance transitions in He-like ions

Figure 11 Energy diagram for 2s and 2p satellite transitions in lithium-like ions corresponding to He- α and He- β transitions in helium-like ions.

(**Figure 11**). The $n'l'$ electron is a spectator electron. Due to the presence of this electron, Coulomb shielding decreases, which results in the transition occurring at a slightly lower energy than that of the resonance transition. Since two electrons are involved in such transitions (one active, one spectator), these lines are also referred to as dielectronic satellites.

The largest separation from a parent line occurs when the spectator electron is in the lowest n level (i.e. $n=2$), when the Coulomb shielding effect is maximum. These satellites are referred to as 2s or 2p satellites. For example, the $1s\ 2s\ 2p-1s^2\ 2s$ transition in Li-like ions will be a 2s satellite for the $1s\ 2p-1s^2$ (He- α) transition in He-like ions (Figure 11). Satellites of H-like ions in the Gabriel notation are denoted by capital letters A, B, ..., J, ... and those of He-like ions are denoted by lower case letters a, b, c, ..., u, v.

Muonic X-rays

When a negatively charged particle (μ^- , π^- , K^- meson) replaces an electron in an atom, a mesonic atom is formed. For example, when a μ^- meson is brought to rest in a target, muonic atoms of the target element are formed by replacement of a valence electron by μ^- . The energy levels in a muonic atom are analogous to the electronic energy levels of an H-like ion except that the muon mass is higher ($m_\mu \sim 207m_e$). The mesonic atom energy levels are related to those of the hydrogen atom by $E(n,l) = Z^2 (M^*/m^*) E_H(n,l)$, where M^* and m^* are the reduced masses of μ^- and the electron, respectively, and $E_H(n,l)$ denotes energy levels in hydrogen. The newly formed muonic atom is thus in a highly excited state and lowers its energy by ejecting electrons by successive Auger processes until the principal quantum number falls to less than 5 (in heavy atoms). At this point, the radiative transition probability becomes more prominent. The energy level differences become of the order of several keV. As a result, X-rays are emitted until the muonic atom reaches its ground state.

The average radius of the lowest (Bohr) orbit of the muonic atom is given by $r \sim (m^*/M^*) (a_H/Z)$ which is considerably smaller than that of a normal atom. For example, for silver, r is 5×10^{-15} m, which is of the order of the nuclear size. As a result, the muon spends

considerable time inside the nucleus. Consequently, the 1s level is strongly affected by the nucleus. This is corroborated by the fact that whereas the Balmer series ($n \rightarrow 2$) transition energies are found to be exactly $Z^2(M^*/m^*)$ times those of the H-atom, the Lyman series ($n \rightarrow 1$) transition energies are lower than expected.

Image Generation

What Is Computed Tomography (CT)?

Computed tomography (CT) uses X-rays to generate cross-sectional, two-dimensional (2D) images of the body. Images are acquired by rapid rotation of the X-ray tube 360° around the patient. The transmitted radiation is then measured by a ring of sensitive radiation detectors located on the gantry around the patient (**Figure 1**). The final image is generated from these measurements utilizing the basic principle that the internal structure of the body can be reconstructed from multiple X-ray projections. The technique has become one of the primary imaging techniques for the evaluation of trauma, cancer, and other serious pathologies.

Early CT scanners acquired images a single slice at a time (sequential scanning). However during the 1980s, significant advances in technology heralded the development of slip-ring technology, which enabled the X-ray tube to rotate continuously in one direction around the patient. This contributed to the development of helical or spiral CT.

During a spiral CT, the X-ray tube rotates continuously in one direction while the table on which the patient is lying is mechanically moved through the X-ray beam. The transmitted radiation thus takes on the form of a helix or spiral. Instead of acquiring data one slice at a time, information can be acquired as a continuous volume of contiguous slices (**Figures 2(a)** and **2(b)**). This allows larger anatomic regions of the body to be imaged during a single breath hold, thereby reducing the possibility of artifacts caused by patient movement. Faster scanning increases patient throughput, and also increases the

probability of a diagnostically useful scan in patients who are unable to fully cooperate during the investigation.

Nearly all scanners in current clinical practice utilize both spiral and multidetector technology (MDCT). Multiple rows of detector rings (4–256) on the gantry allow even quicker coverage and even finer spatial resolution by reconstructing multiple slices for each tube rotation (**Figures 3(a)** and **3(b)**).

How Is a CT Image Produced?

Every acquired CT slice is subdivided into a matrix of 512×512 volume elements (voxels). During the period of the scan, each voxel is traversed by numerous X-ray photons, and the intensity of the transmitted radiation is measured by the multiple rows of detectors. From these intensity readings, the density or attenuation value of the tissue at each point in the slice can be calculated. Specific attenuation values are then assigned to each individual voxel and the final image reconstructed as a corresponding matrix of picture elements (pixels).

What Is a Hounsfield Unit or CT Number?

Each pixel is assigned a numerical value (CT number), which is the average of all the attenuation values

Figure 1 Ring of detectors (fourth generation). Patient in cross-section.

Figure 2 (a) Single slice system (one ring). (b) Single slice helical CT. The X-ray tube rotates continuously and the patient moves through the X-ray beam at a constant rate.

Figure 3 (a) Multidetector system (four rings shown here). (b) Multislice helical CT.

Figure 4 The Hounsfield scale of CT numbers.

contained within the corresponding voxel. This number is compared to the attenuation value of water and displayed on a scale of arbitrary units termed Hounsfield units (HU) after Sir Godfrey Hounsfield.

This scale assigns water an attenuation value (HU) of zero. The range of CT numbers is normally 2000 HU wide, although some modern scanners have a greater range of HU up to 4000. Each number represents a shade of gray with +1000 (white) and -1000 (black) at either end of the spectrum (Figure 4).

Window Level (WL) and Window Width (WW)

Although the range of CT numbers recognized by the computer may be 2000, the human eye cannot accurately distinguish between 2000 different shades of gray. Therefore to allow the observer to interpret the image, only a limited number of HU are displayed. A clinically useful gray scale is achieved by setting the WL and WW on the computer console to a suitable range of HUs, depending on the density of the tissue being viewed.

Figure 5 The two images demonstrate identical anatomical sections, viewed at different window settings. (a) A window level of +40 with a window width of 350 that depicts the anatomy of the mediastinum. The lung parenchyma is obscured. (b) A window level of -600 with a window width of 1500 Hounsfield units, enabling details of the lung parenchyma to be viewed.

The term window level represents the central HU of all the numbers within the WW.

The WW covers the HU of all the tissues of interest and these are displayed as various shades of gray. Tissues with CT numbers outside this range are displayed as either black or white. Both WL and WW can be set independently on the computer console, and their respective settings affect the final image display.

For example, when performing a CT examination of the chest, a WW of 350 and a WL of +40 are chosen to

Figure 6 (a) Pitch is low. The table moves less for each tube revolution so the resulting image is sharper. (b) Pitch is high. The table moves further for each revolution so the resulting image is more blurred. The helix is stretched.

image the mediastinum (soft tissue), whereas an optimal WW of 1500 and a WL of -600 are used to assess the lung fields (predominantly air).

Figures 5(a) and **5(b)** demonstrate identical anatomical sections, viewed at different window settings. **Figure 5(a)** demonstrates a WL of +40 with a WW of 350 that depicts the anatomy of the mediastinum. The lung parenchyma is obscured. **Figure 5(b)** demonstrates a WL of -600 with a WW of 1500 HUs, enabling details of the lung parenchyma to be viewed.

What Is Pitch?

Pitch is the distance measured in millimeters that the table moves during one complete rotation of the X-ray tube, divided by the slice thickness (millimeters). Increasing the pitch by increasing the table speed reduces dose and scanning time, but at the expense of decreased image resolution (**Figures 6(a)** and **6(b)**).

Image Reconstruction

The acquisition of volumetric data using MDCT means that the images can be postprocessed in a variety of ways appropriate to the clinical situation. For example:

- *Multiplanar reformatting (MPR)*. By taking a section through the 3D array of CT numbers acquired within a series of contiguous slices, the sagittal, coronal, and

Figure 7 The three images demonstrate a multitrauma patient and illustrate lacerations to the liver and right kidney as well as fractures of the pelvis in the axial (a), sagittal (b), and coronal (c) planes. *Note:* The quality of Figure 7(a) is degraded by the patient's arm.

oblique planes can be viewed along with the standard axial orthogonal plane.

Figures 7(a)–7(c) demonstrate a multitrauma patient and illustrate lacerations to the liver and right kidney as well as fractures of the pelvis in the axial (**Figure 7(a)**), sagittal (**Figure 7(b)**), and coronal (**Figure 7(c)**) planes. The quality of **Figure 7(a)** is degraded by the patient's arm.

- **3D imaging.** Reconstructed computer data enable the depiction of both external and internal structures of organs. The data can be projected as a 3D model to display spatial information or surface characteristics (termed volume and surface rendering, respectively).

For example, the technique of CT colonography (CTC) or virtual colonoscopy is now routinely used to depict the colonic mucosa in patients unable to undergo conventional invasive optical colonoscopy.

- **Figures 8(a) and 8(b)** demonstrate axial and coronal views of a colonic polyp. **Figure 8(c)** demonstrates a rendered luminal view comparable to that which would be observed during conventional colonoscopy.
- **CT angiography (CTA).** Following intravenous contrast enhancement, images are acquired in the arterial phase and then reconstructed and displayed in either a 2D or a 3D format. The noninvasive technique is commonly used for imaging the aorta, renal, coronary,

Figure 8 (a) Axial and (b) coronal views depicting a colonic polyp. (c) A rendered luminal view comparable to that would be observed during conventional colonoscopy.

and cerebral arteries and provides no additional radiation burden to the operator. In addition, conventional angiography only provides information regarding the internal lumen of the vessel, whereas CTA can delineate pathology within the different vessel wall layers and also displays the surrounding body structures. Modern MDCT can image the coronary arteries in a single heart beat with little or no risk of adverse effects to the patient.

Figure 9(a) demonstrates a 2D angiogram derived from a 3D reconstruction and a significant stenosis of the proximal right coronary artery (arrow). **Figure 9(b)** is a surface rendered image derived from the same dataset. **Figure 9(c)** is a comparative image obtained during a

conventional invasive coronary angiogram that confirms the stenosis.

CTA is also now the first line diagnostic investigation of the cerebral arteries in cases of subarachnoid brain hemorrhage caused by a suspected aneurysm.

Figure 10(a) demonstrates the volume rendered image of a normal cerebral angiogram after digital removal of the skull vault. **Figure 10(b)** demonstrates an aneurysm of the distal left internal carotid artery.

Contrast Media

Differences in contrast between the various tissues of the body can be improved by the use of various types of contrast media. These contrast media mostly contain

Figure 9 (a) A two-dimensional angiogram derived from a three-dimensional reconstruction and a significant stenosis of the proximal right coronary artery (arrow). (b) A surface-rendered image derived from the same dataset. (c) A comparative image obtained during a conventional invasive coronary angiogram that confirms the stenosis.

substances with a high atomic number atom and thus increase the attenuation value of the organ they opacify.

- **Oral contrast.** The bowel is routinely opacified during many CT examinations of the abdomen and pelvis because the attenuation value of the bowel is similar to other surrounding anatomical structures, therefore potentially obscuring pathology. Various types of contrast media are routinely used including 'positive' (high attenuation) contrast agents such as dilute barium- or iodine-based preparations. These are normally drunk by the patient 24 and 1 h before an examination and opacify the proximal and distal gastrointestinal tract. Alternatively 'negative' (low attenuation) contrast agents such as water ($HU = 0$) can

be used to improve mucosal detail (**Figures 11(a)** and **11(b)**).

- **Intravenous contrast.** These media contain iodine-based compounds that are injected to opacify the vascular tree in different phases, depending on the rate and volume of contrast injection and the timing of image acquisition.

- Arterial opacification is maximal at approximately 20 s with venous enhancement rising to a peak at approximately 70 s post injection.

The level of intravascular enhancement then declines as the contrast equilibrates with the various tissues of the body before being excreted via the kidneys. The different enhancement phases are used to image various organs depending on the indication for CT

Figure 10 (a) The volume-rendered image of a normal cerebral angiogram after digital removal of the skull vault. (b) An aneurysm of the distal left internal carotid artery.

examination. MDCT scanners, because of their speed, are able to acquire images during each vascular phase and thus increase the information obtained from a study (Figures 12(a) and 12(b)).

- *Air*. It can also be used as a negative contrast agent, for example, to facilitate imaging of the large bowel – CTC (see Figures 8(a) and 8(b)).

Dual Modality Imaging

Dual modality imaging involves the combination of different imaging techniques. The techniques can be combined *de novo* or imaging can be performed by one modality after initial introduction of a contrast agent using another imaging technique. Positron emission

Figure 11 (a) Positive oral contrast. (b) Negative oral contrast.

tomography combined with MDCT (PET/CT) is an example of the former, whereas CT arterial portography (CTAP) is an example of the latter technique.

Positron Emission Tomography (PET)/CT. The technique measures metabolic activity in tissues and is very useful for the detection of malignant and inflammatory pathologies where intracellular glucose uptake is increased. The radio-pharmaceutical most commonly used is 18-FDG (18-fluoro-deoxy-D-glucose) although other metabolically active substances can be radiolabeled, thus increasing the diagnostic potential of the modality.

Both PET and CT imaging can be performed in the same machine, thus providing superimposed or colocalized CT and PET images of pathology in a single examination.

Figure 12 Part (a) demonstrates multiple arterially enhancing liver metastases. Part (b) taken at a similar level to part (a) in the portal venous phase; the liver metastases are no longer visible, as they have the same attenuation as the normal liver.

The study produces a complementary, overlapping display of anatomical and functional/metabolic information, which can be used in the accurate diagnosis and follow-up of cancer patients (see **Figures 13(a)–13(d)**).

Figure 13(a) shows coronal CT reformat demonstrating thickening of the lower esophagus (arrow). **Figure 13(b)** shows the corresponding PET image demonstrating increased tracer activity within the tumor of the lower esophagus; note the tracer excretion to the kidneys and bladder. **Figure 13(c)** shows fused or coregistered PET/CT images demonstrating excellent

correlation between the anatomic and functional modalities. **Figure 13(d)** shows fused axial image demonstrating the esophageal tumor and normal liver uptake, thus excluding liver metastases.

Advantages and Disadvantages of CT

Advantages

- CT is now widely available in all hospitals.
- New technology allows rapid image acquisition with excellent resolution, thus enabling faster and more accurate diagnostic evaluation of patients over a wide spectrum of clinical indications.
- Acquired CT data can be manipulated, resulting in complex reconstructed multiplanar and 3 D images.

Disadvantages

- *Radiation.* Although small doses of radiation, such as those used in conventional plain film radiography, cause lesser degree of harm, long-term data from the follow-up of atomic bomb survivors and nuclear workers indicate that relative high-dose diagnostic imaging investigations (including CT) do entail a small but significant health risk (**Table 1**). The detrimental radiation effects are described as either deterministic or stochastic in nature.

Deterministic side effects are directly dose related and involve cataracts and skin burns that occur if a significant radiation dose is incurred.

Stochastic effects are less defined and relate to the theoretical chance of a specific side effect, such as a radiation-induced cancer, developing as a result of a given radiation exposure. Stochastic effects of low-dose radiation exposure are controversial with debate about whether a threshold exists, below which radiation has no detrimental and even a possible beneficial effect termed 'radiation hormesis.'

All radiation risks need to be considered on a population rather than on an individual basis. Approximately 3 million CT scans were performed in the United Kingdom during the year 2005–06 when compared to 69 million scans in the United States.

MDCT, however, contributes 75% of the total dosage from radiology-induced exposure with 2006 UK data demonstrating a collective population dose of 28 000 man Sieverts. Application of the IRCP risk factor to fatal cancer cases results in the conclusion that diagnostic radiology contributes to the induction of 1400 fatal cancers during 1 year with 750 directly attributable to MDCT. Although there is a clear medical justification for MDCT in patients with potentially serious pathology, the statistics do question the routine use of MDCT in the asymptomatic

Figure 13 (a) Coronal CT reformat demonstrates thickening of the lower esophagus (arrow). (b) Corresponding PET image demonstrates increased tracer activity within the tumor of the lower esophagus; note the tracer excretion to the kidneys and bladder. (c) Fused or coregistered PET/CT images demonstrate excellent correlation between the anatomic and the functional modalities. screening population. A recent statement from the UK Committee on Medical Aspects of Radiation in the Environment (COMARE) concluded that services offering the whole body MDCT in asymptomatic individuals should cease immediately.

However as MDCT technology further develops, dose reduction techniques will also evolve, raising the possibility of population-based MDCT screening

programs for in particular the diagnosis of colonic cancer, lung cancer, and occult heart disease.

- **Artifacts.** An artifact is a ghost feature or appearance that is visualized on an image. They occur in all imaging modalities and may be unavoidable. Recognizing the presence of various artifacts is important to avoid the misdiagnosis of pathology. However with the increasing speed of image acquisition during a single

Table 1 Radiation doses

<i>Diagnostic procedure</i>	<i>Typical effective dose (mSv)</i>	<i>Equivalent number of CXR</i>	<i>Approximate equivalent period of background radiation</i>
CXR	0.02	1	3 days
CT head	2.0	100	10 months
CT chest	8	400	3.6 years
CT abdomen/pelvis	10	500	4.5 years

Note: UK average background radiation = 2.2 mSv per year; regional averages range from 1.5 to 7.5 mSv per year. mSv, millisieverts.

breath hold many artifacts are being minimized or eliminated.

Artifacts may be divided into the following:

- *Motion*. From movement during a scan and most commonly seen due to patient breathing.
- *Streak (Beam hardening)*. Dark ‘streaks’ visualized behind high-density objects, for example, dental amalgam and metallic joint replacements.
- *Partial voluming*. Different attenuation values within a single voxel lead to ‘averaging’ of data. For example, a small dark object located within a larger light space may be seen as a shade of gray.
- The relative poor tissue contrast when compared to other modalities such as MRI contrast can lead to diagnostic difficulty. This may occur in thin adults and children due to the lack of intra-abdominal fat separating the various tissue planes.
- CT scanners remain expensive.
- The use of contrast media may lead to complications, including allergic reactions and renal toxicity.

Conclusion

MDCT remains one of the most rapidly evolving diagnostic imaging modalities and has in many areas replaced the role of more invasive techniques. The widely available minimally invasive modality is acceptable to a majority of patients, confers no radiation burden to the operator, and allows the remote review of images immediately following acquisition.

The technique, however, does have a number of disadvantages including the relatively high radiation dose to the patient. Any MDCT scan should therefore be performed with an acceptable clinical indication. The central role of the technique in patient management remains secure, although important technological challenges for the future include reducing dose while continuing to maintain images of acceptable diagnostic quality.

J	electronic total angular momentum
m	magnetic quantum number
P	parity quantum number
W	energy separation of Stark splitting
α_2	tensor polarizability
μ_B	Bohr magneton
ψ	atomic wavefunction

Indirect but important usage of Zeeman and Stark effects is found in fundamental physics researches: for example measurements of violation of symmetry in physical laws under time and space inversion known as the T-violation and the parity violation, respectively. Such measurements would eventually give us clues of new physics beyond the standard model of unified electromagnetic and weak interactions.

We present here some selected topics in the application of Zeeman and Stark spectroscopy of atoms in the gas phase with special emphasis on parity-violation experiments.

Introduction

An atomic system is influenced by an external electric and magnetic field. Due to an interaction of the magnetic field with the magnetic moment of an atom, an electronic energy level in the atomic system is shifted in accordance with the formula of the Zeeman effect, while an external static electric field would polarize the atom, resulting in an energy shift referred to as the Stark effect. As the amount of energy shift depends on the magnetic quantum number of the level, the Zeeman and Stark effects resolve the otherwise degenerate energy levels into sublevels. From the pattern of level splitting we can assign the quantum numbers of the observed electronic level. The absolute value of separation between the split levels tells us about the magnetic moment and the polarizability for Zeeman and Stark spectroscopy, respectively.

A straightforward application of Zeeman spectroscopy is a magnetic-field determination using atoms with a known magnetic moment, and one of Stark spectroscopy is a measurement of an electric field using atomic levels with predetermined polarizability. Such measurements are useful when field-measuring probes based on other principles are either unusable or difficult to apply as in the astrophysical environment or in a plasma.

Fundamental Physics Research

A steady state of an isolated atom is described by a quantum-mechanical state specified by the energy and the total angular momentum in accordance with the translation invariance in the time coordinate and the rotational symmetry of the space coordinates, respectively. If physical laws were completely invariant under the parity operation, i.e. space inversion, the wavefunction ψ of the atom remains exactly the same except for its sign, $P\psi$, where $P = \pm 1$. The parity quantum number P introduced in this way would also be a good quantum number in the atomic system if the forces acting on atomic electrons were due only to the classical electromagnetic interaction which is invariant under space inversion. Recent findings in fundamental physics, however, predict that parity is not conserved in the atomic system, though the amount of violation is extremely small.

When an electric field is applied to an atom, the space symmetry is destroyed so that an even-parity state is slightly contaminated by an odd-parity state and vice versa. This makes the otherwise-forbidden E1 transition between the same parity levels to be observable; a Stark-induced transition. The interference term between the Stark-induced E1 transition amplitude and that due to

the intrinsic parity violation changes sign when the direction of the electric field is reversed. Therefore, the parity nonconservation effect can be measured by comparing a small amount of change in the transition rates as we reverse the electric field. There have been several experiments based on this principle to acquire quantitative information of parity violation, the most precise experiments being laser spectroscopy of an atomic beam of Cs under an external electric and magnetic field.

Various attempts are being made to achieve higher accuracy in the parity nonconservation (PNC) measurements. One of the possibilities is to use a heavier atom and to observe a transition to a level with a relatively large amount of parity mixing. Rare earth atoms are deemed as good candidates, because they have many close-lying level pairs of opposite parity. However, there has been no experimental support for them to have a sizable enhancement in parity mixing.

Some examples of Zeeman and Stark spectroscopy of rare earth atoms are shown below. They were obtained in a series of studies aiming at finding the atomic states suitable for the PNC experiment.

In **Figure 1** Stark spectra of samarium atoms are shown. They were obtained by detecting the fluorescence from the level excited with the laser beam. The observed transition is from the ground state ($J=0$) to the 1.9404 eV ($J=1$) excited level, in which J is the electronic total angular momentum.

The strength of the electric field denoted by E is 0.0, 17.2 and 26.1 kV cm^{-1} for the upper, middle and lower part of the figure, respectively. The peaks labelled by open and solid circles correspond, respectively, to the transition from $|m|=0 \rightarrow |m|=0$ and from $|m|=0 \rightarrow |m|=1$, in which m is the magnetic quantum number. We see that each peak for ^{152}Sm and ^{154}Sm is split into two peaks of which the separation increases as the electric field is strengthened. In this case only the Stark effect on the upper level (7G_1) is responsible for the splitting because the lower level has $J=0$. The energy separation of the split is expressed by

$$\Delta W = \frac{3}{2} \alpha_2 J_u E^2 \quad [1]$$

where α_2 is the tensor polarizability and J_u is the electronic total angular momentum of the upper level. The E^2 -dependence of splitting of the ^{154}Sm peak for the same transition is shown in **Figure 2**. It is clearly seen that the energy interval of the splitting is proportional to E^2 . The tensor polarizability is determined from the slope of the straight line: $\alpha_2 = -554.6 \pm 1.3 \text{ kHz (kV)}^{-2} \text{ cm}^2$ for the data shown in **Figure 2**.

The Zeeman spectra for the transition between the 0.0363 eV level ($J=1$) and the 1.9301 eV level ($J=2$) of Sm are shown in **Figure 3**. The peaks labelled by squares and circles correspond to ^{154}Sm and ^{152}Sm . The applied

Figure 1 Stark spectra in an electric field E of 0.0, 17.2 and 26.1 kV cm^{-1} for ^{152}Sm and ^{154}Sm for the transition from the ground state with $J=0$ to the 1.9404 eV level with $J=1$. The energy levels responsible for these spectra are schematically shown in the lower part together with their electronic configuration.

Figure 2 Stark splitting as a function of squared electric field E^2 .

Figure 3 Zeeman spectra of samarium atoms. The applied magnetic field is 0, 115×10^{-4} , 224×10^{-4} and 352×10^{-4} T for (a), (b), (c) and (d), respectively. The peaks represented by squares and circles correspond, respectively, to the transition of ^{154}Sm and ^{152}Sm . The open and solid symbols represent the σ and π components of the transition, respectively.

magnetic field is 0, 115×10^{-4} , 224×10^{-4} and 352×10^{-4} T for the spectra shown in **Figures 3a, 3b, 3c** and **3d**, respectively. The open and solid symbols are for the σ and π components of the transition, respectively. The σ component is the transition associated with a change in magnetic quantum number, $\Delta m = \pm 1$, caused by a photon with its polarization perpendicular to the direction of the magnetic field. The π component is defined as the transition with $\Delta m = 0$. The energy interval, represented by the frequency, f , of Zeeman splitting, is given by the formula

$$f = \mu_B(g_u m_u - g_l m_l)B + C \quad [2]$$

where μ_B is the Bohr magneton, m_u and g_u are the magnetic quantum number and the g -factor for the upper level, respectively, while m_l and g_l are those for the lower level. A constant C gives the original frequency without an external magnetic field. In the case of **Figure 3** the g -factor for the lower level is known to be zero so that the constants g_u , B and C are determined by least-squares fitting of eqn [2] to the relative frequencies among the Zeeman peaks.

Field Measurements

If the g -factors (polarizabilities) are known in advance, it is possible to measure a static magnetic (electric) field by means of the Zeeman (Stark) effect. This is useful

particularly in such situations as in hot plasma and in astronomical objects where the standard field-measuring probes, e.g. a nuclear magnetic resonance probe and a Hall probe, are unusable.

In plasma diagnostics, for example, Stark spectroscopy is used for determining the local electric field. Since the Stark splitting is large for the Rydberg levels, the excitation to the level with high principal quantum number n is used. A small amount of probe atoms mixed in the plasma are excited to metastable states by an electric discharge. They are further pumped up to the Rydberg levels by a laser beam, followed by decay to intermediate levels due to collisional transitions. The fluorescence from the intermediate levels bears information on the electric field at the particular position in the plasma at which the laser is focused with its frequency being scanned. The electric field can also be evaluated from the ratio of the intensity of the forbidden transition induced by the Stark mixing to that of the allowed transition.

Another example is related to astronomical researches: the spectra of starlight usually reveal some emission and absorption lines. The position and the depth of the absorption lines tell us about the atomic species and their relative abundance in the cold outer gas of the star. If a strong field exists in a star, Zeeman and Stark splittings are identifiable in the spectra. From the pattern of absorption or emission lines, it is sometimes

possible to determine the strength of magnetic and electric fields in astronomical objects.

Introduction

The energy difference between the Zeeman and Stark sublevels is usually far smaller than the line width of the optical transition in atoms at normal temperature due to Doppler broadening. Doppler-free techniques are necessary for obtaining the values of g -factors and polarizabilities in optical spectroscopy.

Variations in coherent spectroscopy, such as level crossing, quantum beat and pulsed-field spectroscopy, are examples of Doppler-free techniques. They make use of the interference effect in the transition amplitudes of simultaneous excitation from a level to two closely separated higher levels.

Another technique widely used is atomic beam spectroscopy. In a gas jet ejected from a small orifice, the transverse motion of atoms is much reduced. The line width of the transition induced by a laser beam perpendicularly crossing the atomic beam can be narrow enough to resolve the Zeeman and Stark splitting.

Atomic Beam Spectroscopy

The Doppler effect broadens absorption or emission lines from atoms in the gas phase at thermal equilibrium. Assume that an atom at rest is excited by a photon with wave vector k and de-excited to emit light with angular

frequency ω_0 . If the atom is moving at a velocity v the angular frequency of the emitted light is shifted to a value ω'_0 according to the formula,

$$\omega'_0 = \omega_0 - k \cdot v \quad [1]$$

At thermal equilibrium, the velocities of atoms in the gas phase obey a Maxwellian distribution. This results in the broadened intensity profile around ω_0 as approximately represented by a Gaussian form,

$$I(\omega) = I_0 \exp \left[- \left(\frac{c(\omega - \omega_0)}{\omega_0 v_{th}} \right)^2 \right] \quad [2]$$

where m/c is the velocity of light and $v_{th} = (2k_B T/m_a)^{1/2}$ is the most-probable velocity of atoms with mass m_a , temperature T and Boltzmann constant k_B . The Doppler width defined by the full width at half maximum of the Gaussian profile is

$$\Delta\omega_D = 2\sqrt{\ln 2} \frac{\omega_0 v_{th}}{c} = \left(\frac{\omega_0}{c} \right) \sqrt{\frac{k_B T \ln 2}{m_a}} \quad [3]$$

A case is considered where the atoms are effusing into a vacuum chamber, as shown in **Figure 1**, from an orifice of an oven filled with vapour at a temperature T . Let the atomic beam travel along the z -axis, while the laser beam is parallel to the x -axis. One can reduce the Doppler

Figure 1 Schematic illustration of an atomic beam technique to reduce Doppler broadening. Atomic vapour effuses from a small orifice of an oven. The angular divergence of atoms in the beam is limited to $\theta_0 = \tan^{-1} b/d$ by a slit whose aperture is $2d$ placed at a distance b from the orifice.

broadening by limiting the beam divergence with a slit with a small aperture $2d$ in the x direction at a distance b from the orifice. This makes the beam divergence in the x - z plane smaller than $\theta_0 = \arctan d/b$ and the Doppler broadening is reduced to $\Delta\omega'_D = \Delta\omega_D \sin \theta_0$.

An example of laser spectrometers for Zeeman and Stark spectroscopy using a collimated atomic beam is shown schematically in **Figure 2**. It consists of a continuous-wave (CW) tunable dye laser system, a frequency calibration system, a vacuum chamber with a fluorescence detector and a data acquisition system. The interaction point of the atomic beam with the laser is inside the vacuum chamber.

A magnified view around the interaction point is illustrated in **Figure 3**. The oven made of molybdenum is attached to an end plate of the vacuum chamber in which the pressure is kept to approximately 10^{-6} torr. The oven is heated by a tungsten filament wound around it to eject a gas jet from the orifice with a diameter of 0.8 mm. The temperature can be increased to approximately 1000 K and is monitored with a Pt–Rh thermocouple. The atomic beam is collimated by the slit and led to the interaction point, where the two electrodes made of BK7 glass plates coated with ITO (InSnO_2) on one side are installed to apply the electric field E . The magnetic field B in parallel with the atomic

Figure 2 Typical setup for a laser spectrometer based on the atomic beam method. The apparatus is composed of a continuous-wave (CW) tunable laser system, a laser frequency calibration system, a vacuum chamber and a data acquisition system. The fluorescence light from the excited I_2 molecules in a cell and the excited atoms in the vacuum chamber, and the transmitted light from a Fabry–Perot interferometer (FPI) are detected simultaneously with three photomultiplier tubes (PMTs). The signals are transformed to digital pulses event-by-event and introduced to the inputs of a multi-channel scaler (MCS).

Figure 3 Magnified view around the interaction point of the atomic beam with the laser beam. The oven made of molybdenum is heated by a tungsten filament wound around it to eject a gas jet from the orifice with a diameter of 0.8 mm. The atomic beam is collimated with the slit to a diameter of approximately 4 mm at the interaction point, where the two electrodes for applying the electric field and a pair of Helmholtz coils to produce the magnetic field are installed. The photomultiplier tube (PMT) for detecting the fluorescence light from the atoms and a spherical mirror to collect light are shown.

Figure 4 Typical set of raw data for Zeeman spectrum of samarium atoms with the natural isotopic abundance under the magnetic field of 167.38×10^{-4} T. The number of counts of detected photons per 20 ms is plotted against the MCS channels corresponding to the elapsed time from the starting point of the frequency sweep of the laser. The top part corresponds to the Zeeman spectrum in the transition from the level of $E = 0.18468$ eV ($J = 3$) to the one of $E = 2.0765$ eV ($J = 3$). In the middle and the bottom, the spectrum of $^{127}\text{I}_2$ and the spectrum of the transmitted light from the FPI are shown, respectively.

beam is applied by a set of Helmholtz coils. The fluorescence from the atoms is detected with a photomultiplier tube (PMT) which is cooled to reduce thermal noise. To increase the collection efficiency of the emitted photons, a spherical mirror is installed on the opposite side of the PMT.

Linearly polarized light from a laser is introduced to the inside of the vacuum chamber as shown in **Figure 2**. The CW dye laser is capable of continuously changing its frequency with time, sweeping over a certain frequency range. The laser polarization is adjusted with a half-wave plate when necessary. The signal from the PMT is fed to one of the inputs of a multi-channel scaler (MCS) where the number of counts in each time interval, corresponding to a small frequency segment, is recorded.

The spectra from molecular iodine, $^{127}\text{I}_2$, together with the transmitted light through a Fabry–Perot interferometer (FPI), are recorded synchronously with the fluorescence from the excited atoms to give frequency marks separated by the free spectral range (FSR) of the FPI.

In **Figure 4** a set of raw data obtained in Zeeman spectroscopy of Sm at $B = 167.38 \times 10^{-4}$ T is shown as an example. The uppermost part corresponds to the Zeeman spectra for samarium atoms with the natural isotopic abundance (^{144}Sm : 3.1%, ^{147}Sm : 15.0%, ^{148}Sm : 11.3%, ^{149}Sm : 13.8%, ^{150}Sm : 7.4%, ^{152}Sm : 26.7%, ^{154}Sm : 22.7%) in the transition from the level of $E = 0.18468$ eV ($J = 3$) to the one of $E = 2.0765$ eV ($J = 3$), where J is the electronic total angular momentum. The spectrum of $^{127}\text{I}_2$ and that of the transmitted light from the FPI is shown in the middle and the lowest parts, respectively. After calibration on the horizontal axis and assignment of each peak, the spectra shown in **Figure 5** are obtained for which the Zeeman splitting is completely resolved. Combining the spectra measured with different magnetic field strengths, the g -factor can be determined for either the upper or lower level if one of them has been known in advance.

The Stark spectrum for the same transition at $E = 26.04$ kV cm^{-1} is shown in **Figure 6**. Here again, the splitting is clearly seen thanks to the Doppler-free technique applied here.

Figure 5 Zeeman spectra after calibration on the horizontal axis and peak assignments. The top part of the spectrum is the same as the one shown in **Figure 4**. Magnified spectra of just the area of the peaks for the ^{152}Sm atoms are shown in the middle and the lower parts, in which the magnetic field is 0 T and $167.38 \times 10^{-4} \text{ T}$, respectively. The label above each peak is to indicate the relevant change in the magnetic quantum number, m , to the one with m' , associated with the optical transition.

Coherent Spectroscopy

Although the line widths in the optical transitions observed in atoms in the gas phase at room temperature are larger than the spacing of the Zeeman and Stark splitting, the intervals of the sublevels themselves are scarcely altered by the thermal motion. In the coherent techniques, the relative energies between the sublevels are determined from the observation of the interference of amplitudes of coherent optical excitation followed by de-excitation.

The case of two close-lying levels $|1\rangle$ and $|2\rangle$ is considered. It is possible that the atoms are simultaneously excited to these two levels from a common lower level $|i\rangle$ by a short-pulse laser with the pulse width of $\Delta t < \hbar/|E_2 - E_1|$, where $\hbar$ is the Planck constant divided by 2π . Assume, for simplicity, that the

populations of levels 1 and 2 decay into another common lower level $|f\rangle$, with the same decay constant γ . The total intensity, $I(t)$, of fluorescence emitted from either level will vary with time according to the form

$$I(t) = C e^{-\gamma t} (A + B \cos \omega_{21} t) \quad [4]$$

where A , B and C are constants depending on both the relevant atomic wave functions and the experimental arrangement, and ω_{21} is given by $\omega_{21} = |E_2 - E_1|/\hbar$. This behaves as an exponential decay $\exp(-\gamma t)$ suffering from a sinusoidal modulation with the angular frequency ω_{21} , which is called a quantum beat.

In the case of the Zeeman (Stark) splitting, the Zeeman (or Stark) spectrum is reproduced in a Fourier transform of the time dependence in the fluorescence similar to eqn [4]. It is essential that the time response of

The middle and lower graphs correspond to the spectra for the ^{152}Sm atoms under the electric field of 0 kV cm^{-1} and 26.04 kV cm^{-1} , respectively.

the detection system is fast enough to observe oscillations with the characteristic period $2\pi/\omega_{21}$.

For other measuring techniques based on coherent excitation, see the Further Reading section for details.

ZEKE spectroscopy has been applied to a wide variety of molecular ions, clusters, van der Waals molecules, free radicals, reactive intermediates, and even to elusive transition states of chemical reactions. Examples of such typical applications of high-resolution ZEKE spectroscopy to molecules and clusters are given here. Compared to conventional photoelectron spectroscopy, ZEKE spectroscopy offers greatly increased spectral resolution, allowing the rotational structure of large molecular cations such as the benzene cation and the intermolecular vibrations of molecular clusters like phenol-water to be obtained.

Introduction

NO has been studied extensively by photoelectron spectroscopy. A study using vacuum ultraviolet photoelectron spectroscopy by Turner and co-workers can be compared with a ZEKE study through the $A^2\Sigma^+$ state, using a $1+1'$ photon experiment. As can be seen in **Figure 1**, the resolution is improved by approximately three orders of magnitude, resolving the rotational structure of the NO cation. Benzene and para-difluorobenzene have been studied using time-of-flight photoelectron spectroscopy. These two systems have also been studied using ZEKE spectroscopy. With benzene, rotational resolution has again been obtained, as shown in the comparison in **Figure 2**. The two techniques are compared for para-difluorobenzene in **Figure 3**. Both of the above systems exhibit a breakdown in the

Born–Oppenheimer approximation, and were useful indicators of the Herzberg–Teller, and Jahn–Teller effects.

Smaller Molecules

Iodine (I_2)

Iodine has been studied extensively by ZEKE spectroscopy, including $2+1'$ and $1+2'$ schemes carried out by Cockett and co-workers. In the first case, a number of centrosymmetric Rydberg excited states acted as resonant intermediate states, and in the second case, the valence $B^3\Pi_0$ state was the intermediate. These studies demonstrate how well ZEKE spectroscopy can give a detailed vibrationally resolved spectrum and how auto-ionization is unavoidable in the photoelectron spectroscopy of small molecules.

Figure 1 A comparison between conventional VUV PES and ZEKE spectroscopy on NO; with the latter technique rotational resolution is attained.

Figure 2 The rotationally resolved ZEKE spectrum of benzene compared with time-of-flight PES; again the resolution is improved by several orders of magnitude.

Figure 3 In *para*-difluorobenzene, the vibrational structure of the cation was not fully resolved until the introduction of ZEKE spectroscopy.

The $2 + 1'$ ZEKE spectra of I_2 exhibited non-Franck-Condon behaviour, having intense off-diagonal peaks in v^+ , v , due to vibrational autoionization. **Figure 4** gives the spectra resulting from ionization through the band origin of the $[^2\Pi_{3/2}]_{\text{core}} 5d; 2_g$ state at about $62\,600\text{ cm}^{-1}$, and also through the first three vibrationally excited levels. This state was ionized into the lower spin-orbit

Figure 4 ZEKE spectrum of I_2 recorded through the $[^2\Pi_{3/2}]_{\text{core}} 5d; 2_g$ state; the arrows indicate diagonal transitions, and the asterisks accidental resonances with $A \leftarrow X$ transitions.

state of the ion. Conversely **Figure 5** gives the spectra recorded through the first three vibrational levels of the $[^2\Pi_{1/2}]_{\text{core}} 5d; 2_g$ Rydberg state at about $68\,000\text{ cm}^{-1}$, which was ionized into the upper spin-orbit state of the ion. For the spectrum given in **Figure 4a**, which was through the origin, the $\Delta v = 0$ transition was most intense; the total transition energy to this level is $75\,066 \pm 2\text{ cm}^{-1}$, which is the adiabatic ionization energy (to the ion in its ground vibrational state). There is a weak vibrational progression from the band origin up to $v^+ = 4$. The dominance of the origin peak indicates a minimal change in geometry on ionization. This minimal change in geometry is expected after ionization from the (intermediate) Rydberg state; however, the progression does extend to higher v^+ than is expected merely on the basis of Franck-Condon factors. For the $v = 1$ intermediate state (**Figure 4b**) the non-Franck-Condon behaviour is even more pronounced: the stretching progression can be followed up to $v^+ = 7$; the $\Delta v = 0$ transition remains dominant; however, the peak is of

Figure 5 ZEKE spectrum of I_2 recorded through the $[^2\Pi_{3/2}]_{\text{core}} 5d; 2_g$ state; the arrows indicate diagonal transitions.

about the same intensity as the $\nu^+=0$ peak. For the intermediate states $\nu=2$ (Figure 4c) and $\nu=3$ (Figure 4d) the progressions become longer. Although the spectra show a $\Delta\nu=0$ propensity, a Franck–Condon envelope does not fit the intensity distribution.

The pattern for the vibrational propensity was found to be quite different in the upper spin-orbit state of the ion. In the spectrum recorded through the origin (Figure 5a) the most intense peak corresponds to the $\Delta\nu=0$ transition (to the $\nu^+=0$ level of the ion). The corrected total transition energy to the origin is $80\,266 \pm 2 \text{ cm}^{-1}$; this again corresponds to the adiabatic ionization energy. This result, combined with the ionization energy for the lower $^2\Pi_{3/2}$ spin-orbit state, gives an improved spin-orbit splitting constant for I_2^+ in its ground electronic state of $5197 \pm 4 \text{ cm}^{-1}$. For the upper spin-orbit component, the propensity for the $\Delta\nu=0$ transition remains strong even as the vibrational level of the intermediate is increased. This corresponds to classic Franck–Condon behaviour.

The non-Franck–Condon intensities observed in the lower ($^2\Pi_{3/2}$) spin-orbit state spectrum were attributed

Figure 6 The long Franck–Condon forbidden progression exhibited in the ZEKE spectrum of I_2 of the lower spin-orbit state recorded through $\nu=15$ of the $B^3\Pi_{u0_u^+}$ state.

to autoionization involving another Rydberg series which converges to a higher vibrational state of the upper spin-orbit state in the ion. An interaction between the two Rydberg series, at the ionization threshold of the lower series, gave rise to autoionization from the higher series. No interaction occurs with the upper ($^2\Pi_{1/2}$) spin-orbit state, as there are no nearby Rydberg series.

The $1 + 2'$ photon study, via the valence $B^3\Pi_0$ state, extended the previous work. Long Franck–Condon progressions, arising from the valence character of the intermediate state, are evident in the ZEKE spectra of both spin-orbit components. In the lower spin-orbit component, the vibrational progression extends to at least $\nu^+=62$, and in the upper state as high as $\nu^+=34$. The spectrum in the range $75\,000$ to $80\,000 \text{ cm}^{-1}$ of the lower spin-orbit state, which was recorded via $\nu=15$, is shown in Figure 6.

The vibrational progressions can be adequately simulated through the calculation of Franck–Condon factors; however the observed spin-orbit branching ratio, along with the intensity distribution, reflects a considerable contribution from both spin-orbit and field-induced resonant autoionization processes. Also, accidental resonances at the two-photon level with ion-pair states further perturb the distribution of peak intensities.

HCI

From the ZEKE spectra of hydrogen halides, the rotational-state distribution of the product ion provides a direct measure of the angular momentum of the outgoing electron; this is a sensitive probe of ionization dynamics. Autoionization occurs very readily in these molecules, *via* rotational, vibrational and electronic pathways, and is often evident in the spectra recorded. A further motivation in much of the work on the hydrogen halides has been to investigate the artefacts of autoionization,

particularly the role of rotational and spin-orbit auto-ionization processes. In the cation there is a π -vacancy in the ground electronic configuration. Hence, spin-orbit coupling is evident in the spectra.

HCl has been studied by both single-photon and two-colour multiphoton experiments. The studies focused on the vibrational ground state of the ion and observed a tendency to large changes in angular momentum on ionization, $|\Delta J| \leq 7/2$, indicating a preference for an outgoing d-partial wave. A preference for negative values of angular momentum transfer for both spin-orbit components was observed, which has been evident in many ZEKE spectra which exhibit rotational resolution; this is attributed to rotational autoionization. In the single-photon experiment by White and co-workers, anomalous branch intensities in the ZEKE spectrum were interpreted in terms of field- or dipole-induced mixing of Rydberg states converging on higher-ion rotational levels. Intensity anomalies were observed in the spin-orbit and rotational branching ratios of two-colour ZEKE spectra of de Lange and co-workers recorded *via* the $F^1\Delta_2$, $D^1\Pi_1$ and $f^3\Delta_2$ Rydberg states. The branching ratios were dependent on three experimental parameters:

- (i) The delay time employed between excitation and ionization;
- (ii) The magnitude of the bias electric field;
- (iii) The magnitude of the applied pulsed electric field.

The results were rationalized on the basis of the increasing number of autoionization decay channels that become available to the high- n Rydberg states as each ionization threshold is reached. An analysis of the decay-dependence of the ZEKE spectra *via* the $F^1\Delta_2$ state provided evidence for a non-exponential decay of the high- n Rydberg states.

Studies on the other hydrogen halides have provided similar results; from HF, however, it was concluded that the s-channel dominates the photoionization process as opposed to the d-channel in HCl, HBr and HI.

Ammonia (NH₃)

The NH₃ molecule, when studied by Habenicht and co-workers, was the first polyatomic molecule studied by ZEKE spectroscopy for which full rotational resolution in the cation was achieved. Ionization was achieved by a $2 + 1'$ process, excited through the two-photon transition $\tilde{B} \leftarrow \tilde{X}$. The excitation spectrum for the 2_0^2 transition obtained by REMPI shows clearly resolved rotational structure with a Coriolis interaction giving l-type doubling. This allows for rotational-state selectivity in the intermediate state. The two rotational states corresponding to the *ortho*- ($J_{\text{NH}_3} = 3_1$) and *para*- ($J_{\text{NH}_3} = 3_2$) nuclear spin states of NH₃ were chosen as intermediate states for the ZEKE spectra. These two ZEKE spectra,

Figure 7 The symmetry-based selection rules applied to ZEKE spectroscopy are borne out by the different spectra obtained using the *ortho*- and *para*-nuclear spin states of ammonia.

recorded through the $\tilde{B}$ -state, are given in **Figure 7**, taking the 2_0^2 vibronic transition. There is a clear difference between the spectra obtained for *ortho*- (top spectrum) and *para*-NH₃ (bottom spectrum). The ZEKE spectrum of *ortho*-NH₃ shows one strong transition into the ion rotational state with $N_{K+}^+ = 4_3$, and other transitions with $K^+ = 0$ and 3, which are considerably weaker. On first sight this ZEKE spectrum appears similar to an atomic photoionization spectrum. On the other hand, the ZEKE spectrum of *para*-NH₃ is much fuller giving the strongest lines observed for $K^+ = 1$ and $N_{K+}^+ = 4_4$; also there are weaker transitions into $K^+ = 2$. These spectra are in very good agreement with the symmetry selection rules that apply to ZEKE transitions.

Larger Molecules

Benzene (C₆H₆)

The neutral benzene molecule has a hexagonal, planar structure with D_{6h} symmetry; in the electronic ground state the electronic configuration is $a_{2u}^2 e_{1g}^4$. When benzene is ionized, one of the e_{1g} electrons is removed, leaving one e_{1g} electron unpaired. Thus, the cation has a doubly degenerate $^2E_{1g}$ electronic ground state. The

Jahn–Teller theorem predicts that for any nonlinear polyatomic molecule in a degenerate electronic state, there exists a distortion of nuclear geometry along at least one non-totally symmetric normal coordinate that results in a splitting of the potential-energy function such that the potential minimum is no longer at the symmetrical position.

The structural distortions of the benzene cation have been discussed at length; quantum-chemical *ab initio* calculations predict three equivalent D_{2b} in-plane distortions corresponding to elongation, or compression along three of the twofold-symmetry axes of benzene. These give structures more stable than the hexagonal structure, with an experimentally determined stabilization energy of 266 cm^{-1} . This is approximately half the zero-point energy of the lowest-frequency Jahn–Teller active normal vibration.

For weak Jahn–Teller coupling, the stabilization energy for the distorted symmetry is much smaller than the zero-point energy of the Jahn–Teller active mode. Under collision-free conditions, the three equivalent D_{2b} structures of the cation would dynamically interconvert rapidly, and the ground state of the cation would still be described in the D_{6h} symmetry group. For strong Jahn–Teller coupling the cation would spend much time in one of the three structures, and would therefore be described in D_{2b} . The knowledge of the structure and the symmetry of the isolated benzene cation is desirable not only for testing quantum-mechanical model calculations, it also has a fundamental importance for organic chemistry. Through group-theoretical considerations, rotationally resolved ZEKE spectroscopy gives a clear and unambiguous determination of the symmetry of the cation. Thus, if the molecule were statically distorted to lower symmetry, transitions would appear in the rotationally resolved ZEKE spectra, which are forbidden in the D_{6h} structure. Thus, the observed rotational transitions are a sensitive and clear indication of the symmetry of the cation.

If one quantum of a Jahn–Teller active normal vibration in the benzene cation (these are the modes v_{6-9} with e_{2g} symmetry) is excited, the linear dynamic Jahn–Teller coupling leads to a splitting into two vibronic states with $j = \pm 1/2$ (E_{1g} symmetry) and $j = \pm 3/2$ ($B_{1g} \oplus B_{2g}$ symmetry) vibronic angular momentum. The $j = \pm 3/2$ states are further split by quadratic dynamic Jahn–Teller coupling, but the $j = \pm 1/2$ state remains doubly degenerate.

Detailed vibronic structure is seen in the low-resolution scan of the ZEKE spectrum of benzene, recorded via the 6^1 vibrational level in the S_1 state of the neutral. Bands with fundamental frequencies characteristic of the ν_6 , ν_{16} , ν_4 and ν_1 vibrational modes are seen. However, no harmonic progressions can be observed, with the higher-energy portion of the spectrum exhibiting a highly

irregular and dense system of vibronically active states. The active mode of lowest energy is ν_6 , which is along the coordinate predicted for the Jahn–Teller distortion by *ab initio* methods. A key pair of bands, which appear at about 350 cm^{-1} , corresponding to the ion internal energy, are the B_{1g} and B_{2g} vibronic components of the ν_6 fundamental, shifted to lower energy by linear Jahn–Teller coupling. However, the relative ordering of B_{1g} and B_{2g} is unclear in this spectrum. The conservation of symmetry of the nuclear spin wavefunction restricts the possible transitions to these two vibronic states; thus, depending on the vibronic symmetry, only certain rotational progressions can be observed.

A high-resolution ZEKE scan of the B_{1g} and B_{2g} components of the 6^0 band recorded by exciting through the $6^1, J'_{K'} = 2_2, -1'$, S_1 state is shown in **Figure 8**. In this spectrum, only the $K^+ = 0$ projections of even N^+ are seen in the lower-energy vibronic component, whereas only those from odd N^+ are seen in the higher-energy vibronic component. This effect can be attributed to nuclear spin statistics, and indicates unambiguously that the lower-energy vibronic component has B_{1g} symmetry, and that the higher-energy vibronic component has B_{2g}

Figure 8 In the lower-energy band of benzene, recorded through the $S_1^1 6^1 E_{1u}, 2_2-1'$ state, only even K are observed, whereas in the higher-energy band odd K are observed, indicating rigorously the symmetry of the vibronic state associated with each band.

symmetry. Thus the rotational structure in the ZEKE spectrum has established that the B_{2g} level in the quadratically split $6^1(j=3/2)$ levels of the benzene cation lies above the B_{1g} level.

The cation is apparently distorted to a small extent by quadratic Jahn–Teller coupling in ν_6 . It has been concluded from the rotational intensities in the ZEKE spectrum that the wells in the pseudorotation coordinate correspond to local B_{1g} electronic configurations (the elongated structure) whereas the saddle points are locally B_{2g} (compressed). From the coupling parameters that fit the vibronic structure in the coarse ZEKE spectrum, an energy difference between the stationary states of only 8 cm^{-1} is established. This is much less than the ν_6 zero-point energy of 413 cm^{-1} , indicating that the benzene cation is fluctuational, and therefore must be viewed in D_{6h} symmetry rather than in terms of the three D_{2h} structures with locally non-degenerate electronic configurations.

Toluene

The toluene molecule and its torsional states are classified according to its irreducible representations in the molecular symmetry (MS) group G_{12} , which is isomorphic to the point group D_{3h} . The problem of an unhindered, rigid methyl rotor attached to a rigid frame reduces to a one-dimensional Schrödinger equation with eigenfunctions, $\Psi_{\text{tor}}(\alpha) = (2\pi)^{-1/2} e^{\pm im\alpha}$ and eigenvalues, $E_M = Bm^2$, where B is an effective constant for the methyl-group rotation relative to the rigid molecular framework and $m = 0, \pm 1, \pm 2, \dots$ is the rotational quantum number. In toluene, the torsional potential has sixfold symmetry. A small torsional perturbation of the form $V(\alpha) = (V_6/2)(1 - \cos 6\alpha)$ leaves the $m = \pm 1, \pm 2, \pm 4$ and ± 5 states doubly degenerate but lifts the degeneracy of the $m = \pm 3$ and $m = \pm 6$ levels.

$\alpha = 0$ is defined as an eclipsed geometry, and $\alpha = \pi/6$ as a staggered geometry. The rotor states are termed $0a_1', 1e'', 2e', 3a_2'', 3a_1'', 4e'$, etc. Band intensities in the S_1 – S_0 and cation– S_1 spectra reveal which $|m| = 3$ state lies lower in energy and thus the absolute phase of the torsional potential. For negative V_6 (potential minimum at $\alpha = \pi/6$), $3a_2''$ lies below $3a_1''$, whereas for positive V_6 (potential minimum at $\alpha = 0$), $3a_1''$ lies below $3a_2''$.

Weisshaar and co-workers recorded ZEKE spectra of toluene through different intermediate resonances of S_1 and they are presented in Figure 9. From the assignment it can be shown that there is a positive V_6 with $3a_1''$ lower in energy than the $3a_2''$ torsional state. The torsional states of the toluene cation ($0, 15, 54$ and 75 cm^{-1}) are not very different from the torsional states in the S_1 state ($1, 15, 55$ and 77 cm^{-1}), leading to the conclusion that the torsional barriers in the cation and in S_1 are quite similar.

For both $0a_1' \rightarrow 0a_1'$ and $3a_1'' \rightarrow 0a_1'$ excitations of S_1 , the ZEKE band at 46 cm^{-1} is stronger than the 54 cm^{-1} band.

Figure 9 ZEKE spectra recorded through various torsional levels of the S_1 state in toluene. The label EXC indicates the torsional transition to the intermediate: $S_0 \leftarrow S_1$.

Using the assumption that torsion–electronic coupling allows all $a \rightarrow a$ torsional transitions and forbids $a \rightarrow e$ transitions and the fact that the 47 cm^{-1} band is three times more intense than the 54 cm^{-1} band for ionization through the $3a_1''$ state of S_1 , the 47 cm^{-1} band is assigned to the $3a_1'' \rightarrow 3a_1''$ transition and the 54 cm^{-1} band to $3a_2'' \rightarrow 3a_1''$. These assignments for the ZEKE spectra constitute a major step in understanding large-amplitude motions and the role of torsional–electronic couplings.

Weakly Bound Molecules

Phenol–Methanol

The study of the PhOH–MeOH complex, by Müller-Dethlefs and co-workers, was carried out with a $1 + 1'$ REMPI spectrum. This was difficult to interpret owing to

Figure 10 The striking vibrational progression seen in the ZEKE spectrum of phenol-methanol.

the comparatively dense vibrational structure. Various vibrational levels in the S_1 state were used as intermediate states on the way to ionization. The ZEKE spectrum obtained by exciting *via* the S_1 vibrationless level, given in **Figure 10**, is striking with progressions of about 10 quanta in a low-frequency vibrational mode of 34 cm^{-1} , denoted h_1 , appearing in combination with components of an anharmonic progression of the intermolecular stretch of 278 cm^{-1} . The pattern suggests a rather substantial change of geometry upon ionization. The adiabatic ionization energy was derived as $63\,207 \pm 4\text{ cm}^{-1}$ which is a red shift from the S_0 state of $5421 \pm 8\text{ cm}^{-1}$, indicating a large increase in bond strength. The latter point is also exemplified by the large increase in the energy of the intermolecular stretch compared with 176 cm^{-1} in the S_1 state and 162 cm^{-1} in the S_0 state. Additionally, between the latter components, another set of progressions of the intermolecular mode of 34 cm^{-1} were seen, this time in combination with a third intermolecular mode of 52 cm^{-1} .

The ZEKE spectrum obtained *via* the S_1 state, with one quantum of the lowest-frequency intermolecular mode excited, showed the same vibrations but with a substantially changed Franck-Condon envelope which allowed the identification of a fourth intermolecular mode, denoted h_4 , at 153 cm^{-1} . A slightly different envelope for the 34 cm^{-1} vibration was also obtained when exciting through the S_1 state with one quantum of the intermolecular stretch excited. The other two intermolecular modes of the Ph-MeOH cationic complex were identified from the ZEKE spectrum obtained *via* a combination band; their values being 76 cm^{-1} and 158 cm^{-1} .

I₂-Ar

Iodine-argon was one of the first complexes to be studied in the early jet spectroscopy experiments conducted by

Levy and co-workers in the 1970s. Most of the work carried out on this complex since then has been concerned with the $\tilde{B}^3\Pi_0^+ \leftarrow \tilde{X}^1\Sigma_g^+$ system studied using laser-induced fluorescence (LIF) spectroscopy. This state is not well suited as a resonant intermediate in ZEKE spectroscopy, as it lies only $15\,800\text{ cm}^{-1}$ above the electronic ground state. Since this study a number of *g* and *n*d Rydberg excited states, based upon both spin-orbit states of the $\tilde{X}^2\Pi_{\Omega,g}I_2^+-\text{Ar}$ core, have been characterized using 2 + 1 mass-resolved REMPI spectroscopy, by Cockett and co-workers. These Rydberg states lie between $53\,000$ and $69\,000\text{ cm}^{-1}$ and are better suited as resonant intermediate states for ionization into the two spin-orbit components of the $\tilde{X}^2\Pi_{\Omega,g}$ ionic ground state.

Substantial differences in the binding energy were observed for the 6s, 5d and 6d Rydberg states of the $I_2\text{-Ar}$ complex, which correlate with the degree to which the positive charge of the core is shielded from the argon atom by the Rydberg electron. More-penetrating Rydberg orbitals reduce the charge-induced dipole forces between iodine and argon. The observed binding energy increases are seen in the REMPI spectra as progressive increases in spectral red shifts and intermolecular van der Waals stretching frequencies.

An issue which had been the subject of considerable debate was whether $I_2\text{-Ar}$ adopts a T-shaped or linear geometry. Initial speculation suggested that it should be linear by analogy with the known linear geometry of the ClF-Ar complex. However, the first direct experimental evidence for the geometry of $I_2\text{-Ar}$ emerged from a partially rotationally resolved B-X fluorescence excitation spectrum, which showed that $I_2\text{-Ar}$ adopts a T-shaped geometry. It was also suggested that a linear isomer was responsible for an observed fluorescence excitation continuum underlying the discrete B-X transitions.

The mass-resolved 2 + 1 REMPI spectrum recorded by monitoring the I_2^+-Ar mass channel is shown in **Figure 11**. The spectrum is composed of partially overlapping vibrational progressions arising from the $[\text{}^2\Pi_{3/2}]_c\ 5\text{d};\ 2_g$ (**Figure 11a**; recorded with circularly polarized light) and $[\text{}^2\Pi_{3/2}]_c\ 5\text{d};\ 0_g^+$ (**Figure 11b**; recorded with linearly polarized light) Rydberg states of I_2-Ar . The vibrational structure for both states essentially arises from simultaneous excitation of both the I-I stretch (ν_1) and the I_2-Ar van der Waals stretch (ν_3). For the $[\text{}^2\Pi_{3/2}]_c\ 5\text{d};\ 0_g^+$ state, the progression terminates

abruptly at $\nu_3\nu_1$, which suggests that the complex dissociates at this point. The $\nu_3\nu_1$ band appears at an internal vibrational energy of 758 cm^{-1} , but the spectral red shift of the band origin dictates a lower limit to the zero-point dissociation energy for this state of $563 \pm 5\text{ cm}^{-1}$. Thus, it would appear that the coupling between the two vibrational modes is sufficiently weak to enable the complex to accommodate an excess 195 cm^{-1} of internal energy before it dissociates. This is consistent with the geometry of the complex being T-shaped.

The $[^2\Pi_{3/2}]_c 5d; 2_g$ Rydberg state progression shown in **Figure 11a** has an additional complexity of structure when compared to the progression observed for the 0_g^+ state. For both $v_1=0$ and $v_1=1$, each vibrational band appears significantly broader than observed for the 0_g^+ progression, and on most of the bands, an apparent splitting can be resolved. However, for $v_1=2$ the doublet structure has disappeared and the peaks have adopted the narrower profile seen in the 0_g^+ progression. In fact, the doublet structure arises, not from any splitting of the peaks, but from two partially overlapping vibrational

progressions with near-identical band origins. It appears from the spectrum that one of the progressions terminates at $v_1=1$ while the other continues at least as far as $v_1=2$.

Assuming that the point at which the progression terminates represents the point at which the complex dissociates, the conclusion drawn was that for the shorter progression, the onset of dissociation occurs at 463 cm^{-1} internal vibrational energy (compared with a calculated value for D_0 of about 503 cm^{-1}), while for the longer progression, dissociation occurs at a lower limit of

Figure 12 The ZEKE spectra of $\text{I}_2\text{-Ar}$ recorded through the $[^2\Pi_{3/2}]_{\text{core}} 5d; 2_g$ state. (A) is through the overlapping (0_0^0) vibrational levels, (B) the (3_0^1) levels and (C) the (3_0^2) levels.

655 cm^{-1} . On this basis, a provisional assignment was made of the shorter progression to the linear isomer, for which the van der Waals stretch might be expected to couple more efficiently with the I_2 stretch, and the longer progression to the T-shaped isomer.

Although the REMPI spectrum certainly provided a great deal of circumstantial evidence for the existence of two isomers, the assignment was to be greatly strengthened by extending the study to the ionic state by using ZEKE spectroscopy to probe the $[\text{}^2\Pi_{3/2}]_c\text{ }5\text{d}; 2_g$ Rydberg state in a two-colour $2 + 1'$ ionization scheme, and recording isomer-specific ZEKE spectra. The ZEKE spectra of the ground electronic state of the ion recorded *via* several intramolecular vibrational levels in the $[\text{}^2\Pi_{3/2}]_c\text{ }5\text{d}; 2_g$ Rydberg state show, in each case, two well-separated vibrational progressions (**Figure 12**). As the level of vibrational excitation is increased in the intermediate Rydberg state, so the vibrational activity in the resulting ZEKE spectra increases.

The general propensity for diagonal transitions was consistent with the fairly small changes in geometry that occur on exciting from the Rydberg state to the ion. The experimental observations in this case were consistent with an assignment of the two overlapping Rydberg state progressions to two geometrical isomers. The measured difference in the ionization energies of 43 cm^{-1} for the two isomers provided an indication of their relative stabilities in the ion, with the linear isomer being the more weakly bound.

Introduction

Understanding of chemistry and the chemical bond is greatly influenced by molecular orbital theory. The power of the molecular orbital approach in providing an understanding of the structure and reactivity of molecules lies in its description of chemical bonds. The legitimacy of a molecular orbital description is attested to by the results of molecular electronic spectroscopy. In the single-electron molecular orbital picture, photoionization involves the excitation of an electron from a bound orbital into the ionization continuum. The energy from the photon is partitioned between the kinetic energy of the electron and the ionization energy as in eqns [1] and [2]. Thus by selecting the electron kinetic energy a spectrum can be recorded.

$$h\nu = E_{\text{ionization}} + E_{\text{kinetic}} \quad [1]$$

$$E_{\text{ionization}} = E_{\text{internal}}(\text{ion}) - E_{\text{internal}}(\text{neutral}) \quad [2]$$

To a first approximation the ionization energy is equal to the energy of the orbital from which the electron originates in the ground-state molecule. This is known as Koopmans' theorem, and allows each signal in the spectrum to be assigned to an orbital. Koopmans' theorem provides evidence that molecular orbitals are conceptually valid and has assumed a very important place in the development of our understanding of the electronic structure of molecules.

Koopmans' theorem is limited by its neglect of molecular orbital reorganization, and transitions between states of correct symmetry species that are allowed; hence it can be quite misleading. Thus a better picture is

to say that, at low resolution, the signals observed correspond to different electronic states in the cation. At higher resolution, fine structure in the photoelectron spectrum corresponds to the vibronic levels of the cation; a broad band, with significant vibronic structure, indicates a large change in structure between the neutral molecule and the cation. This is due to the improved overlap with vibrational overtones, arising as a result of the Franck–Condon principle. An ionization scheme for conventional PES is given in Figure 1.

Figure 1 An ionization scheme for conventional PES.

Figure 2 The setup for conventional photoelectron spectroscopy.

The setup for a conventional photoelectron spectrometer is illustrated in **Figure 2**. In modern spectrometers the sample is introduced in a molecular beam, with a very low temperature. The major restriction on the resolution of PES, however, arises through the practical resolution of the geometrical or time-of-flight (TOF) photoelectron analysers used to analyse the kinetic energy; in order to have a reasonable signal strength this is about 10 meV (80 cm^{-1}).

The energy of the radiation source used in photoelectron spectroscopy determines the configuration of the ion. If a high-energy source is used as in X-ray photoelectron spectroscopy (XPS), the electron is emitted from a core orbital, whereas ultraviolet photoelectron spectroscopy (UVPS) will only give signals from the valence orbitals of molecules with relatively low ionization energies.

ZEKE Photoelectron Spectroscopy

The method of ZEKE spectroscopy was invented by Müller-Dethlefs, in 1984, to bypass the resolution limitation. The technique uses a delayed electric field pulse to extract only the electrons ionized without kinetic energy, as shown in **Figure 3**. A signal is only seen when the radiation used is precisely that required to excite the electrons to the ionization threshold; thus, in theory, the resolution is limited only by the bandwidth of the radiation used in ionization. Dye lasers are used as the source of radiation in the ZEKE experiment, as these can have a very low bandwidth (of the order of 0.05 cm^{-1}). This allows the prospect of resolving rotational states of larger

Figure 3 (a) A pulsed laser beam ionizes the sample, and kinetic electrons are scattered randomly. (b) A delayed electric field pulse is used to extract ZEKE electrons from the ionization volume.

molecular cations. A graphic illustration of the greater resolving power of ZEKE spectroscopy can be seen in **Figure 4** in which the conventional photoelectron spectrum of I_2 is compared with a ZEKE spectrum.

The photon energy from a dye laser, even after frequency-doubling, is normally insufficient to ionize a molecule; hence the experiment involves a multiphoton process, normally via a resonant intermediate state. An advantage from this resonant intermediate state selection is, for instance, that different vibrational levels of the intermediate state can be selected, thus allowing the Franck–Condon factors for ionization to change. In order to find the intermediate states a resonance-enhanced multi-photon ionization (REMPI) spectrum must first be recorded. This is usually done by incorporating a TOF mass spectrometry apparatus into the ZEKE photoelectron spectroscopy apparatus. For the extraction of the heavier ions a high-voltage pulse ($\sim 1\text{ kV}$) is used and the ion signal is detected by multichannel plates. The REMPI signal can be mass-selected to ensure that it represents an excited state of the appropriate species; this property is very important when studying van der Waals clusters in molecular

Figure 4 The improvement in resolution gained by using ZEKE spectroscopy.

beams. The ionization scheme for a two-colour $1 + 1'$ REMPI spectrum is shown in **Figure 5**.

With the exception of electron photodetachment from anions, it was soon realized that the ZEKE signal detected in a typical experiment does not actually arise from direct photoionization. With the application of an electric field to extract the ZEKE electrons there is a lowering of the ionization energy by the Stark effect, resulting in the ionization of high- n Rydberg states ($n > 100$) which are said to be within a 'magic region' lying about 5 to 10 cm^{-1} below each ion threshold, as indicated in **Figure 6**. As it turned out, the pulsed-field ionization of the Rydberg states sometimes leading to the name ZEKE-PFI, is in fact preferable to the 'true' ZEKE technique, since the neutral Rydberg states are less susceptible to stray electric fields in the apparatus than the 'true' ZEKE electrons. The ionization scheme for ZEKE is given in **Figure 7**. In the case of ZEKE photodetachment, the only mechanism by which one can obtain a signal is the detection of free electrons with zero kinetic energy.

A great deal of research effort has been expended in trying to understand the nature of the Rydberg states in the 'magic region'. The origin of the exceptionally long lifetime of the ZEKE Rydberg states has been a matter of some considerable debate and although the discussion is continuously evolving, a degree of consensus has been reached concerning the principal contributory effects. The extended lifetime is attributed to a combination of the effects of small homogeneous fields (which typically originate from electronic equipment in the laboratory) and inhomogeneous electric fields (associated with regions of localized charge in the spectrometer, e.g. ions). The highly diffuse nature of high-lying Rydberg states renders them susceptible to l and m_l mixing through

Figure 5 An ionization scheme for a $1 + 1'$ REMPI experiment.

Figure 6 (a) the Rydberg states converge on the ionization energy. (b) the long-lived states in the 'magic' region are field-ionized by the extraction pulse.

external perturbations. Stray DC electric fields may cause substantial I mixing through the Stark effect, while inhomogeneous fields inducing m_l randomization arise from the presence of ions in low to medium concentrations. This slows down the rate of intramolecular relaxation considerably due to the conservation of angular momentum, as depicted in **Figure 8**. In the 'magic region' the Rydberg electron acquires a non-penetrating character and no longer interacts with the positive-ion core. Conversely, in the lower-lying Rydberg states the Rydberg electron still undergoes regular collisions with the core, which leads to intramolecular relaxation processes such as predissociation into neutral fragments and autoionization. This decay of the lower Rydberg states during the typical delay times used in ZEKE experiments is the underlying reason why peak widths observed in ZEKE spectroscopy are limited, even when high field strengths are used.

If laser-limited resolution is required, it is necessary to design sophisticated field-ionization schemes. The resolution benchmark is the rotationally resolved ZEKE spectrum of benzene. From this it was demonstrated that the benzene cation is planar and adequately described in the D_{6h} molecular point group, despite being subject to Jahn–Teller distortion. ZEKE spectroscopy has also been

Figure 7 An ionization scheme for ZEKE spectroscopy.

successfully applied to studies of the vibrational structure of large organic molecules, molecular and metal clusters, and hydrogen-bonded systems. One of the more routine strengths of the technique is that ionization energies can be determined with an accuracy comparable to that of Rydberg extrapolations but with less experimental effort.

Variation of the slope of the pulse allows the spectral resolution to be adjusted according to the laser

Figure 8 (a) Collisions between the Rydberg electron and the core in lower Rydberg states cause decay by intramolecular processes such as predissociation. (b) The nonpenetrating character of higher Rydberg states results in a longer lifetime.

Figure 9 The effect of slope risetime on the resolution: in (a) the fast pulse gives a low resolution as a large slice of the Rydberg manifold is ionized; in (b) the slower pulse enables the detection of much smaller slices of the manifold, giving a higher resolution at the cost of signal strength.

bandwidth limitations and to the demands of the system under study (whether one requires vibrational or rotational resolution). **Figure 9** shows schematically the effect of pulse-slope risetime on the TOF of the corresponding electrons produced by PFI. A fast pulse

generates all the signal within a narrow TOF distribution, whereas a slow pulse spreads the different 'slices' of Rydberg states into a broader TOF distribution. Thus, for a particular TOF gate a smaller spectral 'Rydberg slice' will be collected when the photon energy of the

light source is scanned for a slow rather than for a fast risetime pulse.

There are many ways to improve the resolution by varying the pulse sequence. The use of an extraction pulse causes the $2l+1$ degeneracy of a given state to be lifted, due to the Stark effect. Those with a negative m_l are raised in energy, and those with a positive m_l are lowered in energy; this has the effect of broadening the signal about the field-free ionization energy. However, it has been shown that under field ionization the Stark states shifted to the blue (with negative m_l values) have a longer lifetime than those shifted to the red. Hence the signal seen arises principally from states which have been red shifted. This can be accounted for using a multi-step staircase-like extraction pulse, to determine exactly the ionization energy under field-free conditions. It has also been observed that if a double extraction pulse is used, the second being of opposite polarity to the first, the Stark states which were blue shifted, and therefore were not ionized by the first pulse, kept the same orientation, and were red shifted with respect to the second pulse. The consequence of this fractional Stark-state selection is that a narrower slice of Stark states is selected, and a higher-resolution signal is obtained.

A typical experimental setup for a ZEKE experiment is shown schematically in **Figure 10**. It consists of a laser system and a vacuum apparatus which includes the molecular beam source, the extraction plates and a μ -metal-shielded flight tube with electron/ion detectors (dual multichannel plates) at each end. In a typical two-colour experiment, both dye lasers (often frequency-doubled) are pumped simultaneously by an excimer laser or a Nd:YAG laser. The first dye laser excites a specific vibronic or rovibronic level of the intermediate state and the second laser ionizes the molecules or promotes them into long-lived Rydberg states ($n > 150$) converging to (ro)vibronic levels of the electronic ground state or an electronically excited state of the cation. After a delay time of a few microseconds, an extraction pulse is applied by either a simple electric pulsing device or an arbitrary-function generator. The electrons are detected at the

multichannel plates and their time of flight is recorded with boxcar integrators or a transient digitizer by setting narrow time gates (10–30 ns).

Intensities in ZEKE Spectra

The selection rules for ZEKE transitions are governed by the usual principle that the transition-moment integral must be totally symmetric to give a non-zero intensity. For ZEKE transitions these can be affected by coupling to other Rydberg states. For rotational transitions one has to consider the possibility of transfer of angular momentum to the Rydberg electron; hence the selection rule for the quantum number representing the total angular momentum excluding spin is no longer $\Delta N = \pm 1, 0$. One model to account for the intensities of the rotational transition is the spectator model. In the spectator model it is assumed that the Rydberg electron wave function is atomic hydrogen-like, with angular momentum l_0 and has no interaction with the core; hence the selection rules for N'' , the total angular momentum of the Rydberg state, and N^+ , the total angular momentum of the ion, are bound by the triangle condition $|N'' - N^+| \leq l_0 \leq |N'' + N^+|$. The intensities of ionizing transitions in the spectator model are dependent only on the transitions into the Rydberg state; a more complicated model is the compound model, where it is not assumed that the Rydberg state is initially fully decoupled from the core; hence further transfer of angular momentum can occur before the extraction pulse.

A further factor which affects the intensity of transitions is the role of autoionization from the Rydberg states. When a given Rydberg state is near the ionization threshold of another, lower-energy Rydberg series, the state has a shortened lifetime with respect to autoionization; as a consequence the intensity of higher-energy Rydberg series is usually depleted. In rotationally resolved spectra this is observed as a propensity for negative changes in angular momentum.

Mass-Selected ZEKE Spectroscopy

An extension of ZEKE spectroscopy is mass-analysed threshold ionization (MATI), 'photoelectron spectroscopy without photoelectrons'. This is effectively the same experiment; for every ZEKE electron produced, there must be a cation, and in MATI detection a signal is recorded from these ions. It is much harder to separate the ions produced from pulsed-field ionization of the ZEKE Rydberg states from the ever-present directly produced ions. Ions are much heavier than electrons and hence move more slowly, so a higher-voltage extraction pulse is required for the separation and the subsequent extraction and selection of the cations. The obvious

Figure 10 A schematic representation of the ZEKE apparatus.

advantage of this combination of ZEKE with mass spectrometry is the ability to select the cations on the basis of their mass.

The MATI signal also allows the study of fragmentation processes. It is interesting that at levels of ion internal energy at which a complex dissociates, the ZEKE spectrum can still be observed. When only looking at the ZEKE signal, it is not obvious that such a fragmentation has occurred; however, by looking at the MATI signal, fragmentation can be observed, as the spectrum switches from the parent cation mass channel to a fragment mass channel. This gives a direct measure of the dissociation energy of the cation. Predissociation can also be observed directly by this technique, and the dissociation products observed, which is useful for obtaining a more complete rovibronic structure of molecules.

Another development in photoionization spectroscopy is the technique called photoinduced Rydberg ionization (PIRI). In this, the neutral molecule absorbs radiation to produce a high- n Rydberg state, as well as prompt ions. The prompt ions are separated using a delayed electric pulse, and the remaining Rydberg states, rather than being field-ionized, as in MATI, are photoexcited to form core-excited Rydberg states, which autoionize, and can be separated from the remaining Rydberg states. This technique effectively gives the absorption spectrum of the cation; also the problems arising from Stark shifts are no longer relevant as the molecules are not field-ionized.

Appendix 2. Tables of SI and related units

SI base units

<i>Quantity</i>	<i>Name</i>	<i>Symbol</i>
Length	Meter	m
Mass	Kilogram	kg
Time	Second	s
Electric current	Ampere	A
Thermodynamic temperature	Kelvin	K
Amount of substance	Mole	mol
Luminous intensity	Candela	cd

Units in use with the international system

<i>Name</i>	<i>Symbol</i>	<i>Value in SI units</i>
Minute	min	1 min = 60 s
Hour	h	1 h = 60 min = 3600 s
Day	d	1 d = 24 h = 86 400 s
Degree	°	1° = ($\pi/180$) rad
Minute	'	1' = (1/60)° = ($\pi/10\,800$) rad
Second	"	1" = (1/60)' = ($\pi/648\,000$) rad
Litre	l	1 l = 1 dm ³ = 10 ⁻³ m ³
Tonne	t	1 t = 10 ³ kg

CGS units with special names

<i>Name</i>	<i>Symbol</i>	<i>Value in SI units</i>
Erg	erg	1 erg = 10 ⁻⁷ J
Dyne	dyn	1 dyn = 10 ⁻⁵ N
Poise	P	1 P = 1 dyn s cm ⁻² = 0.1 Pa s
Stokes	St	1 St = 1 cm ² s ⁻¹ = 10 ⁻⁴ m ² s ⁻¹
Gauss	Gs, G	1 Gs corresponds to 10 ⁻⁴ T
Oersted	Oe	1 Oe corresponds to (1000/4 π) A m ⁻¹
Maxwell	Mx	1 Mx corresponds to 10 ⁻⁸ Wb
Stilb	sb	1 sb = 1 cd cm ⁻² = 10 ⁴ cd m ⁻²
Phot	ph	1 ph = 10 ⁴ lx

SI prefixes

<i>Factor</i>	<i>Prefix</i>	<i>Symbol</i>
10 ²⁴	yotta	Y
10 ²¹	zetta	Z
10 ¹⁸	exa	E
10 ¹⁵	peta	P
10 ¹²	tera	T
10 ⁹	giga	G
10 ⁶	mega	M
10 ³	kilo	k
10 ²	hecto	h
10 ¹	deca	da
10 ⁻¹	deci	d
10 ⁻²	centi	c
10 ⁻³	milli	m
10 ⁻⁶	micro	μ
10 ⁻⁹	nano	n
10 ⁻¹²	pico	p
10 ⁻¹⁵	femto	f
10 ⁻¹⁸	atto	a
10 ⁻²¹	zepto	z
10 ⁻²⁴	yocto	y

SI-derived units

Quantity	SI unit			
	Name	Symbol	Expression in terms of other units	Expression in terms of SI base units
Frequency	Hertz	Hz		s^{-1}
Force	Newton	N		$m\ kg\ s^{-2}$
Pressure, stress	Pascal	Pa	$N\ m^{-2}$	$m^{-1}\ kg\ s^{-2}$
Energy, work, quantity of heat	Joule	J	$N\ m$	$m^2\ kg\ s^{-2}$
Power, radiant flux	Watt	W	$J\ s^{-1}$	$m^2\ kg\ s^{-3}$
Quantity of electricity, electric charge	Coulomb	C		$s\ A$
Electrical potential, potential differential, electromotive force	Volt	V	$W\ A^{-1}$	$m^2\ kg\ s^{-3}\ A^{-1}$
Capacitance	Farad	F	$C\ V^{-1}$	$m^{-2}\ kg^{-1}\ s^4\ A^2$
Electric resistance	Ohm	Ω	$V\ A^{-1}$	$m^2\ kg\ s^{-3}\ A^{-2}$
Conductance	Siemens	S	$A\ V^{-1}$	$m^2\ kg^{-1}\ s^3\ A^2$
Magnetic flux	Weber	Wb	$V\ s$	$m^2\ kg\ s^{-2}\ A^{-1}$
Magnetic flux density, magnetic inductance, magnetic field	Tesla	T	$Wb\ m^{-2}$	$kg\ s^{-2}\ A^{-1}$
Inductance	Henry	H	$Wb\ A^{-1}$	$m^2\ kg\ s^{-2}\ A^{-2}$
Luminous flux	Lumen	lm		$cd\ sr$
Illuminance	Lux	lx	$lm\ m^{-2}$	$m^{-2}\ cd\ sr$
Dynamic viscosity	Pascal second	$Pa\ s$		$m^{-1}\ kg\ s^{-1}$
Moment of force	Metre newton	$N\ m$		$m^2\ kg\ s^{-2}$
Surface tension	Newton per metre	$N\ m^{-1}$		$kg\ s^{-2}$
Heat flux density, irradiance	Watt per square metre	$W\ m^{-2}$		$kg\ s^{-3}$
Heat capacity, entropy	Joule per kelvin	$J\ K^{-1}$		$m^2\ kg\ s^{-2}\ K^{-1}$
Specific heat capacity, specific entropy	Joule per kilogram kelvin	$J\ kg^{-1}\ K^{-1}$		$m^2\ s^{-2}\ K^{-1}$
Specific energy	Joule per kilogram	$J\ kg^{-1}$		$m^2\ s^{-2}$
Thermal conductivity	Watt per meter kelvin	$W\ m^{-1}\ K^{-1}$		$m\ kg\ s^{-3}\ K^{-1}$
Energy density	Joule per cubic metre	$J\ m^{-3}$		$m^{-1}\ kg\ s^{-2}$
Electric field strength	Volt per metre	$V\ m^{-1}$		$m\ kg\ s^{-3}\ A^{-1}$
Electric charge density	Coulomb per cubic metre	$C\ m^{-3}$		$m^{-3}\ s\ A$
Electric displacement, electric flux density	Coulomb per square metre	$C\ m^{-2}$		$m^{-2}\ s\ A$
Permittivity	Farad per metre	$F\ m^{-1}$		$m^{-3}\ kg^{-1}\ s^4\ A^2$
Permeability	Henry per metre	$H\ m^{-1}$		$m\ kg\ s^{-2}\ A^{-2}$
Molar energy	Joule per mole	$J\ mol^{-1}$		$m^2\ kg\ s^{-2}\ mol^{-1}$
Molar entropy, molar heat capacity	Joule per mole kelvin	$J\ mol^{-1}\ K^{-1}$		$m^2\ kg\ s^{-2}\ K^{-1}\ mol^{-1}$

Appendix 3. Wavelength scale

Appendix 4. Color, wavelength, frequency, wave number, and energy of light

<i>Color</i>	λ/nm	ν/Hz	$\bar{\nu}/\text{cm}^{-1}$	E/eV	$E/\text{kJ mol}^{-1}$
Infrared	1000	$3.00 \cdot 10^{14}$	$1.00 \cdot 10^4$	1.24	120
Red	700	$4.28 \cdot 10^{14}$	$1.43 \cdot 10^4$	1.77	171
Orange	620	$4.84 \cdot 10^{14}$	$1.61 \cdot 10^4$	2.00	193
Yellow	580	$5.17 \cdot 10^{14}$	$1.72 \cdot 10^4$	2.14	206
Green	530	$5.66 \cdot 10^{14}$	$1.89 \cdot 10^4$	2.34	226
Blue	470	$6.38 \cdot 10^{14}$	$2.13 \cdot 10^4$	2.64	254
Violet	420	$7.14 \cdot 10^{14}$	$2.38 \cdot 10^4$	2.95	285
Near ultraviolet	300	$1.00 \cdot 10^{15}$	$3.33 \cdot 10^4$	4.15	400
Far ultraviolet	200	$1.50 \cdot 10^{15}$	$5.00 \cdot 10^4$	6.20	598

Appendix 5. Magnetic susceptibilities at 25 °C

	κ	χ
Water	$-9.0 \cdot 10^{-5}$	$-9.0 \cdot 10^{-9}$
Benzene	$-7.2 \cdot 10^{-6}$	$-8.2 \cdot 10^{-9}$
Cyclohexane	$-7.9 \cdot 10^{-6}$	$-1.02 \cdot 10^{-8}$
Carbon tetrachloride	$-8.9 \cdot 10^{-6}$	$-5.4 \cdot 10^{-9}$
NaCl (s)	$-1.39 \cdot 10^{-5}$	$-6.4 \cdot 10^{-9}$
Cu (s)	$-9.6 \cdot 10^{-5}$	$-1.07 \cdot 10^{-9}$
S (s)	$-1.29 \cdot 10^{-5}$	$-6.2 \cdot 10^{-9}$
Hg (l)	$-2.85 \cdot 10^{-5}$	$-2.1 \cdot 10^{-9}$
$\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ (s)	$1.76 \cdot 10^{-4}$	$7.7 \cdot 10^{-8}$
$\text{MnSO}_4 \cdot 4\text{H}_2\text{O}$ (s)	$2.64 \cdot 10^{-3}$	$8.12 \cdot 10^{-7}$
$\text{NiSO}_4 \cdot 7\text{H}_2\text{O}$ (s)	$4.16 \cdot 10^{-4}$	$2.01 \cdot 10^{-7}$
$\text{FeSO}_4(\text{NH}_4)_2 \cdot \text{SO}_4 \cdot 6\text{H}_2\text{O}$ (s)	$7.55 \cdot 10^{-4}$	$4.06 \cdot 10^{-7}$
Al (s)	$2.2 \cdot 10^{-5}$	$8.2 \cdot 10^{-9}$
Pt (s)	$2.62 \cdot 10^{-4}$	$1.22 \cdot 10^{-8}$
Na (s)	$7.3 \cdot 10^{-6}$	$7.5 \cdot 10^{-9}$
K (s)	$5.6 \cdot 10^{-6}$	$6.5 \cdot 10^{-9}$

The CGS values of the susceptibility (per gram) are obtained by forming $1000\chi/4\pi$, and the value per gram mole from $1000\chi M_r/4\pi$.

Data were revised 2006 from a variety of sources; density and refractive index are at 20°C, other parameters mainly at 25°C; exceptions occur when the solvent is not liquid at these temperatures; MP and BP are means or best values from the NIST Chem WebBook.

Appendix 8. Chemical tables

Important Abbreviations and Acronyms

A	adenine
AA	anisylacetone
AAO	acetaldehyde oxime
AC	acetate
Ac	acetyl [$\text{CH}_3\text{CO}-$]
acac	acetylacetone
ACTH	adrenocorticotrophic hormone (corticotropin)
ADMA	alkyldimethylamine
ADP	adenosine 5'-diphosphate
AIBN	azobisisobutyronitrile
Ala	alanine (A)
Am	amyl
AMP	adenosine 5'-monophosphate
AN	acetonitrile
APS	adenosine 5'-phosphosulfate
Ar	aryl
Arg	arginine (R)
Asn	asparagine (H)
Asp	aspartic acid (D)
ATA	anthranilamide
ATP	adenosine 5'-triphosphate
BA	benzyladenine
BaP (BAP)	benzo[a]pyrene
BBP	benzyl butyl phthalate
BHC	benzene hexachloride
BHT	2,6-di- <i>t</i> -butyl-4-methylphenol
bipy	2,2'-bipyridyl
Bn	benzyl (also Bz, BZL, or Bnz)
BN	benzonitrile
Boc	<i>t</i> -butoxycarbonyl
BOM	benzyloxymethyl [$\text{PhCH}_2\text{OCH}_2-$]
BON	β -oxynaphthoic acid
BPG	butyl phthalyl butyl glycolate
Bs	brosylate [$\text{BrC}_6\text{H}_4\text{SO}_2-$]
BSA	<i>O,N</i> -bistrimethylsilyl acetamide
BTB	benzoyltri- <i>n</i> -butylammonium
Bu	butyl
Bz	benzoyl
C	cytosine
p CBA	<i>p</i> -carboxybenzaldehyde
Cbz	carbobenzoyloxy [$\text{PhCH}_2\text{OCOC}-$]
CD	cyclodextrin
CDP	cytidine 5'-diphosphate

CE	cyclohexyl
CMP	cytidine 5'-monophosphate
CoA	coenzyme A
Cp (or cp)	cyclopentadiene
12-Crown-4	1,4,7,10-tetraxacyclododecane
CTA	citraconic anhydride
Cys	cysteine (C)
DAA	diacetone acrylamide
DAP	dodecylammonium propionate
DCB	dicyanobenzene
DCEE	dichloroethyl ether
DDD	2,2'-dihydroxy-6,6'-dinaphthyl disulfide
DDH	1,3-dibromo-5,5-dimethylhydantoin
DDM	diphenyldiazomethane
DOT	1,1-bis(<i>p</i> -chlorophenyl)-2,2,2-trichloroethane
DEA	<i>N,N</i> -diethylaniline or diethyl amine
DEC	diethylaminoethyl chloride hydrochloride
DHA	dehydroacetic acid
DHP	dihydropyran
Diglyme	diethylene glycol dimethyl ether
Diox	dioxane
DMAc	<i>N,N</i> -dimethylacetamide
DMAA	<i>N,N</i> -dimethylacetoacetamide
DME	1,2-dimethoxyethane (glyme)
DMF	dimethylformamide
DML	dimyristoyl lecithin
DMS	dimethylsiloxane
DMSO	dimethyl sulfoxide
DMSO2	dimethyl sulfone
DMT	dimethyl terephthalate
DNA	deoxyribonucleic acid
DNF	2,4-dinitrofluorobenzene
DOCA	deoxycorticosterone acetate
DPG	2,3-diphosphoglycerate
DPL	dipalmitoyl lecithin
dpm	dipivaloylmethanato
DPPH	diphenylpicrylhydrazyl
DST	disuccinimidyl tartrate
DTBN	di- <i>t</i> -butyl nitroxide
E	trans config. (entgegen)
EAA	ethyl acetoacetate
EAK	ethyl amyl ketone
EBA	<i>N</i> -ethyl- <i>N</i> -benzylaniline

(Continued)

Appendix 8. (Continued)

Important Abbreviations and Acronyms

EBBA	<i>N</i> -(p-methoxybenzylidene)-p-butylaniline	MAA	methoxyacetic acid
EDC	ethylene dichloride	Man	mannose
EDTA	ethylenediaminetetraacetic acid	MBBA	<i>N</i> -(p-methoxybenzylidene)-p-butylaniline
EGS	ethylene glycol bis(succinimidyl succinate)	MCA	monochloroacetic acid
en	ethylenediamine	Me	methyl
Et	ethyl	MEM	β -methoxyethoxymethyl
EVA	ethylene vinyl acetate	Mes	mesityl = 2,4,6-trimethylphenyl
FA	furfuryl alcohol	Met	methionine (M)
FAD	flavin adenine dinucleotide	MMH	methylmercuric hydroxide
FMA	fluorescein mercuric acetate	MM	methoxymethyl
Fmoc	9-fluorenylmethoxycarbonyl	Ms	mesyl = methanesulfonyl = CH_3SO_2-
Fuc	fucose	MSA	methanesulfonic acid
G	guanine	MTPA	α -methoxy- α -trifluoromethylphenylacetic acid
Gal	galactose	MVK	methyl vinyl ketone
GDP	guanosine 5'-diphosphate	NAC	<i>N</i> -acetyl
Glc	glucose	NAD(P)	nicotinamide adenine dinucleotide (phosphate)
Gln	glutamine (Q)	NAD(P)H	nicotinamide adenine dinucleotide (phosphate)
Glu	glutamic acid (E)	NAI	<i>N</i> -acetylimidazole
Gly	glycine (G)	NCA	<i>N</i> -chloroacetamide
Glyme (glyme)	1,2-dimethoxyethane	NI	nonaflate ($\text{C}_9\text{F}_9\text{SO}_2-$)
HAB	4,4'-bis(heptyloxy)benzene	NM	nitromethane
Hex	hexane (or hexyl) or hexose	NMA	<i>N</i> -methylacrylamide
HFA	hexafluoroacetone	NMF	<i>N</i> -methylformamide
His	histidine (H)	Ns	<i>p</i> -nitrobenzenesulfonyl
HMDS	hexamethyldisilazide	NTA	nitrioltriacetic acid
HMPA	hexamethylphosphoramide	OCBA	<i>o</i> -chlorobenzoic acid
HMPT	hexamethylphosphorous triamide	OCT	<i>o</i> -chlorotoluene
HOAB	<i>p</i> -n-heptyloxyazobenzene	ODCB	<i>o</i> -dichlorobenzene
HOAc	acetic acid	P	polymer substituent
Hyp	hydroxyproline	PAA	<i>p</i> -azoxyanisole
IH	immobilized histamine	PAS	<i>p</i> -aminosalicylic acid
IHP	inositolhexaphosphate	PBA	pyrene butyric acid
Ile	isoleucine (I)	PBLG	poly(L-benzyl μ -glutamate)
IMP	inosine 5'-monophosphate	PC	propylene carbonate
IPN	isophthalonitrile	PCA	perchloric acid
KDP	potassium dihydrogen phosphate	PCB	polychlorinated biphenyl
LAH	lithium aluminum hydride (LiAlH_4)	PCP	pentachlorophenol
LAP	leucine aminopeptidase	PDMS	polydimethylsiloxane
LDH	lactic dehydrogenase	PEG	polyethylene glycol
Leu	leucine (L)	PET	
Lys	lysine (K)	Ph	phenyl
M	metal	Phe	phenylalanine (F)
MA	maleic anhydride	phen	1,10-phenanthroline

(Continued)

Appendix 8. (Continued)

Important Abbreviations and Acronyms

PMA	poly(methacrylic acid)
PMMA	poly(methyl methacrylate)
POC	cyclopentylloxycarbonyl
POM	poly(oxyethylene)
PPA	polyphosphoric acid
Pr	propyl
Pro	proline (P)
PS	polystyrene
PTFE	polytetrafluoroethylene
PVA	poly(vinyl alcohol)
PVC	poly(vinyl chloride)
PVF	poly(vinyl fluoride)
PVP	poly(vinyl pyrrolidone)
Pyr (or Py)	pyridine
RNA	ribonucleic acid
SDS	sodium dodecyl sulfate
Ser	serine (S)
SLS	sodium lauryl sulfate
T	thymine
TAB	trimethylammonium bromide (TMAB)
TBE	tetrabromoethane
TCA	trichloroacetic acid
TCNQ	tetracyanoquinodimethane
TEA	triethylamine
TI	triflate [CF_3SO_2^-]
TFA	trifluoroacetic acid

THF	tetrahydrofuran
THP	tetrahydropyran
Thr	threonine (T)
TIPS	trisopropylsilyl
TMB	<i>N,N,N',N'</i> -tetramethylbenzidine
TMM	trimethylenemethane
TMS	tetramethylsilyl
TMU	tetramethylurea
TNM	tetranitromethane
TNT	2,4,6-trinitrotoluene
Tol	<i>p</i> -tolyl
TP	thymolphthalein
TPC	thymolphthalein complexone
TPE	tetraphenylethylene
Tr	trityl = triphenylmethyl
Triglyme	triethylene glycol dimethyl ether
TRIS	tris(hydroxymethyl)aminomethane
Trp	tryptophan (W)
Ts	tosyl = <i>p</i> -toluenesulfonyl
Tyr	tyrosine (Y)
U	uracil
UTP	uridine 5'-triphosphate
Val	valine (V)
Xyl	xylose
Z	<i>cis</i> configuration (zusammen)

Equilibrium Constants at 25°C

Dissociation constants of weak bases

Formula	Name	K_b	Formula	Name	K_b
NH_3	ammonia	1.8×10^{-5}	$C_{10}H_{14}N_2$	nicotine	$\begin{cases} 7.4 \times 10^{-7} (K_1) \\ 1.4 \times 10^{-11} (K_2) \end{cases}$
NH_2OH	hydroxylamine	9.1×10^{-9}	PH_3	phosphine	1×10^{-14}
CH_3NH_2	methylamine	4.4×10^{-4}			

Concentration Units for Solutions

Name	Symbol	Definition
Weight percent	wt %	(Grams of solute per grams of solution) $\times 100$
Mole fraction	X_A	Moles of A per total number of moles
Molar	M	Moles of solute per liter of solution
Normal	N	Equivalents of solute per liter of solution
Formal	F	Formula weights of solute per liter of solution
Molal	m	Moles of solute per kg of solvent
Weight formal	f	Formula weight of solute per kg of solvent

Appendix 10. Chemical tables

Acronyms and Abbreviations in Quantum Chemistry and Molecular Modeling

AM1	Austin Method 1, a modified MNDO method (semi-empirical)
AMBER	Assisted Model Building and Energy Refinement, P. Kollman's empirical force field for biopolymers
AMFI	Atomic Mean Field approximation for SO coupling
AO	Atomic Orbital
ARCS	Aromatic Ring Current Shielding
BOMD	Born-Oppenheimer Molecular Dynamics simulation
CC	Coupled Cluster methods (ab initio)
CCSD(T)	Coupled Cluster method at Singles, Doubles, Triples level
CDFT	Current Density Functional Theory (ab initio)
CFT	Crystal Field Theory
CHARMM	CHemistry at HARvard Macromolecular Mechanics, empirical force field implementation of M. Karplus
CHF	Coupled Hartree-Fock perturbation theory
CI	Configuration Interaction
CNDO	Complete Neglect of Differential Overlap (semi-empirical)
CNDO/ <i>n</i>	Complete Neglect of Differential Overlap (level <i>n</i> = 1 or 2)
CNDO/2H	CNDO/2 modified for hydrogen bonding
CPMD	Car-Parrinello Molecular Dynamics simulation
CSGT	Continuous Set of Gauge Transformations (ab initio)
DFT	Density Functional Theory (ab initio)
DFTB	Density Functional Tight Binding method
DHF	relativistic four-component Dirac-Hartree-Fock method
DZ	Double Zeta, a basis set consisting of two STOs for each atomic orbital
EH	Extended Hückel theory
EHT	Extended Hückel Theory
EOM	Equation Of Motion
FEMO	Free-Electron Molecular Orbitals
FPT	Finite Perturbation Theory
GGA	Generalized Gradient Approximation (DFT)
GIAO	Gauge-Including Atomic Orbitals, also used: Gauge-Invariant or Gauge-Independent (ab initio)
GIPAW	Gauge-Including Projector-Augmented Waves (ab initio)
GTO	Gaussian Type atomic Orbital
HF	Hartree-Fock method for self-consistent fields
HFC(C)	HyperFine Coupling (Constant)
HMO	Hückel Molecular Orbitals
HOMO	Highest Occupied Molecular Orbital
IGAIM	Individual Gauge for Atoms In Molecules (ab initio)
IGLO	Individual Gauge for Localized Orbitals (ab initio)
INDO	Intermediate Neglect of Differential Overlap (semi-empirical)
JWKB	Jeffreys-Wentzel-Kramers-Brillouin, a semiclassical approximation to quantum mechanics
K-LMG	split-valence basis set defined with K, L, M numbers of Gaussians
LCAO	Linear Combination of Atomic Orbitals (ab initio)
LDA	Local Density Approximation (DFT)
LUMO	Lowest Unoccupied Molecular Orbital (see HOMO)

Appendix 10. (Continued)

Acronyms and Abbreviations in Quantum Chemistry and Molecular Modeling

MCSCF	M ult C onfiguration S elf C onsistent F ield (ab initio)
MD	M olecular D ynamics (with any method)
MINDO	M odified I ntermediate N eglect to D ifferential O verlap (semi-empirical)
MINDO/<i>n</i>	M odified I ntermediate N eglect of D ifferential O verlap (<i>n</i> = 1-3, semi-empirical)
MINDO/3H	MINDO/3 modified for hydrogen bonding
MM	M olecular M echanics (with empirical force field)
MM<i>n</i>	N. L. Allinger's empirical force field for small molecules (<i>n</i> = integer)
MNDO	M odified N eglect of D ifferential O verlap (semi-empirical)
MNDO/H	MNDO modified for hydrogen bonding
MO	M olecular O rbital
MP2	M øller-Plesset 2nd-order perturbation calc. (ab initio)
MR-CI	M ulti- R eference C onfiguration I nteraction
NDDO	N eglect of D iatomic D ifferential O verlap
NICS	N ucleus- I ndependent C hemical S hift (aromaticity)
OPLS	O ptimized P otentials for L iquid S imulations, W. Jorgensen's empirical force field for biopolymers
PM3	P arameterized M ethod 3 (a modification of AM1)
PPP	P ariser- P arr- P ople method (semi-empirical)
QSAR	Q uantitative S tructure- A ctivity R elationship
REX	R elativistic E Xtended Hückel MOs
RHF	R estricted H artree- F ock method (for SCF calculations)
SCF	S elf- C onsistent F ield
SCRIF	S elf- C onsistent R eaction F ield for free radicals
SD	S pin- D ipolar term
SO	S pin- O rbital coupling
SOMO	S ingly O ccupied M olecular O rbital
SOS	S um O ver S tates perturbation theory
STO	S later T ype O rbital basis set (ab initio)
STO-<i>n</i>G	S later T ype O rbital as a sum of <i>n</i> Gaussians
TFD	T homas- F ermi- D irac method, a statistical treatment of electron density
UCHF	U n C oupled H artree- F ock perturbation method
UHF	U nrestricted H artree- F ock method for SCF calculations
VB	V alence B ond theory
VSEPR	V alence- S hell E lectron P air R epulsion, a theory of molecular geometry
VWN	V osko, W ilk, N usair parameterization for LDA
WKB	W entzel- K ramers- B rillouin method, a semiclassical approximation to quantum mechanics
ZDO	Z ero D ifferential O verlap (semi-empirical)
ZFS	Z ero- F ield S plitting
ZINDO	Z erner's I NDO method
ZORA	Z ero- O rders R egular A pproximation

Appendix 11. Standard potentials in aqueous solutions

Selected half-reaction potentials are listed in order of increasingly positive (anodic) assignments, providing a convenient guide to redox couples in a given range of standard potentials. The synopsis consists of two tables, one each for acid and basic solutions, which have been advisedly restricted to selected half-reactions.

Standard potentials in acid solutions

Couple	E° (V)
$(3/2)\text{N}_2 + \text{H}^+ + \text{e}^- \rightarrow \text{HN}_3$	-3.10
$\text{Li}^+ + \text{e}^- \rightarrow \text{Li}$	-3.045
$\text{K}^+ + \text{e}^- \rightarrow \text{K}$	-2.925
$\text{Rb}^+ + \text{e}^- \rightarrow \text{Rb}$	-2.925
$\text{Cs}^+ + \text{e}^- \rightarrow \text{Cs}$	-2.923
$\text{Ba}^{2+} + 2\text{e}^- \rightarrow \text{Ba}$	-2.92
$\text{Ra}^{2+} + 2\text{e}^- \rightarrow \text{Ra}$	-2.916
$\text{Sr}^{2+} + 2\text{e}^- \rightarrow \text{Sr}$	-2.89

–C ₆ H ₅	Ethanol	246 (4.30)		

Appendix 14. Typical UV absorption maxima of aromatic and heteroaromatic Compounds

Bands for different compounds arising from the same transition type are grouped together. For bands with fine structure, only $\lambda_{\max}$ of the band centre is given

<i>Compound</i>	<i>Solvent</i>	<i>$\lambda_{\max}$ nm (log E in brackets)</i>				
Benzene	Cyclohexane		183 (4.66)	204 (3.90)	256 (2.30)	
Naphthalene	Ethanol	167 (4.48)	190 (4.00)	220 (5.12)	286 (3.97)	312 (2.46)
Anthracene	Cyclohexane	186 (4.51)	221 (4.16)	256 (5.26)	375 (3.95)	(buried)
Naphthacene	Benzene	187 (4.20); 211 (4.64)	230 (3.23)	272 (5.26)	474 (4.10)	
Azulene	Cyclohexane	700 (2.48)	193 (4.26)	236 (4.34)	269 (4.67)	357 (3.60)
Phenanthrene	Cyclohexane		222 (4.38)	252 (4.82)	292 (4.20)	345 (2.32)
Quinoline	Cyclohexane			228 (4.60)	270 (3.50)	315 (3.40)
Isoquinoline	Cyclohexane			218 (4.80)	265 (3.62)	313 (3.26)
Acridine	Ethanol			250 (5.30)	358 (4.00)	
Pyridine	Hexane	195 (3.88)	251 (3.30)		270 (2.65)	
Pyrimidine	Cyclohexane		243 (3.31)		298 (2.48)	
Pyrazine	Cyclohexane		260 (3.80)		327 (2.00)	
Pyridazine	Cyclohexane		246 (3.11)		340 (2.50)	
Purine	Water	< 220 (3.48)	263 (3.90)			
Pyrrole	Hexane	210 (3.71)			240 (2.48)	
Furan	Hexane	205 (3.81)				
Thiophene	Hexane	231 (3.85)				
Imidazole	Ethanol	207 (3.70)				
Pyrazole	Ethanol	210 (3.50)				
Isoxazole	Ethanol	211 (3.60)				
Thiazole	Ethanol	240 (3.60)				

Appendix 15. Common isotopes for Mössbauer spectroscopy

Isotope	Natural abundance (%)	Spin states		E_γ (keV)	Source isotope	Half-life	Line width (mm s^{-1})	Sign of $\Delta R/R$
		(<i>gd</i>)	(<i>ex</i>)					
^{57}Fe	2.2	1/2	3/2	14.4	^{57}Co	270 d	0.2	– ve
^{119}Sn	0.63	1/2	3/2	23.8	$^{119\text{m}}\text{Sn}$	240 d	0.8	+ ve
^{121}Sb	2.1	5/2	7/2	37.2	$^{121\text{m}}\text{Sb}$	77 y	1.8	– ve
^{127}I	100	5/2	7/2	57.6	$^{127\text{m}}\text{Te}$	105 d	2.0	– ve
^{129}I	0.6	7/2	5/2	27.7	$^{129\text{m}}\text{Te}$	33 d	0.8	+ ve
^{99}Ru	12.8	3/2	5/2	89.4	^{99}Rh	16 d	0.3	+ ve
^{193}Ir	61.5	1/2	3/2	73.0	$^{193\text{m}}\text{Os}$	30 h	1.4	+ ve
^{197}Au	100	3/2	1/2	77.3	$^{197\text{m}}\text{Pt}$	18 h	1.9	+ ve

Appendix 16. NMR frequency table

NMR Frequencies vs. Magnetic Field Strengths - sorted by atomic number

Isotope	Spin	Nat. Abund. (%)	Receptivity		Larmor Frequencies (MHz) vs. Magnetic Field Strengths (Tesla)														
			Natural rel. ^{13}C	Molar rel. ^1H	Freq. to 3 decimals are experimental for IUPAC Standards; freq. to 2 dec. are calculated from magn. moments

PBu_3^{I} – 32.5	PMe_2F 186	PF_5 – 80.3	$[\text{PF}_6]^-$ – 145
PBu_3^{I} – 45.3	PMe_2H – 99	PCl_5 – 80	$[\text{PCl}_4]^+$ 86
PBu_3^{S} 7.9	PMe_2Cl 96.5	MePF_4 – 29.9	$[\text{PCl}_6]^-$ – 295
PBu_3^{I} 63	PMe_2Br 90.5	Me_3PF_2 – 158	Me_2PF_3 8.0

Appendix 18. Chemical shift ranges and standards for selected nuclei

Nucleus	Spin	Chemical shift range δ (ppm)	Standard
^1H	1/2	12 to –1	SiMe_4
^6Li	1	5 to –10	1 M LiCl in H_2O
^7Li	3/2	5 to –10	1 M LiCl in H_2O
^{11}B	3/2	100 to –120	$\text{BF}_3 \cdot \text{OEt}_2$
^{13}C	1/2	240 to –10	SiMe_4
^{15}N	1/2	1200 to –500	MeNO_2
^{17}O	5/2	1400 to –100	H_2O
^{19}F	1/2	100 to –300	CFCl_3
^{23}Na	3/2	10 to –60	1 M NaCl in H_2O
^{27}Al	5/2	200 to –200	$[\text{Al}(\text{H}_2\text{O})_6]^{3+}$
^{29}Si	1/2	100 to –400	SiMe_4
^{31}P	1/2	230 to –200	H_3PO_4
^{43}Ca	7/2	40 to –40	CaCl_2
^{51}V	7/2	0 to –2000	VOCl_3
^{67}Zn	5/2	100 to –2700	ZnClO_4
^{77}Se	1/2	1600 to –1000	SeMe_2
^{93}Nb	9/2	0 to –2000	NbCl_6^-
^{99}Ru	3/2	3000 to –3000	$\text{RuO}_3/\text{CCl}_4$
^{119}Sn	1/2	5000 to –3000	SnMe_4
^{121}Sb	5/2	1000 to –2700	$\text{Et}_4\text{NSbCl}_6$
^{129}Xe	1/2	2000 to –6000	XeOF_4
^{133}Cs	7/2	300 to –300	CsBr
^{195}Pt	1/2	9000 to –6000	Na_2PtCl_6
^{199}Hg	1/2	500 to –3000	HgMe_2^a

^aHighly poisonous (see Chemical & Engineering News 6/1997).

Appendix 19. NMR tables

Abbreviations and Acronyms Used in Magnetic Resonance

ACCORDION	2D technique, simultaneous incrementing of evolution and mixing times
ADA	Alternated Delay Acquisition
ADC	Analog-to-Digital Converter
ADEQUATE	Astonishingly Sensitive Double Quantum Transfer Experiment
ADLF	Adiabatic Demagnetization in the Laboratory Frame
ADRF	Adiabatic Demagnetization in the Rotating Frame
AEE	Average Excitation Energy approximation
AJCP	Adiabatic J Cross Polarization
APT	Attached Proton Test
AQ	Acquire
ARP	Adiabatic Rapid Passage
ASIS	Aromatic Solvent-Induced Shift
ASTM	American Society for Testing and Materials
BB	Broadband, as in decoupling
BIRD	Bilinear Rotation Decoupling
BLEW	A windowless multiple-pulse decoupling sequence
BPP	Bloembergen/Purcell/Pound (theory)
BR-24	Burum & Rijn (pulse sequence)
BURP	Band-selective Uniform Response Pulse
BWR	Bloch/Wangsness/Redfield (theory)
CAMELSPIN	Cross-relaxation Appropriate for Molecules Emulated by Locked SPINs
CCPPA	Coupled Cluster Polarization Propagator Approximation
CH-COSY	Carbon-Hydrogen Correlation Spectroscopy
CHESS	Chemical Shift Selective Imaging Sequence
CHF	Coupled Hartree-Fock molecular orbital calculations
CIDEP	Chemically Induced Dynamic Electron Polarization
CIDNP	Chemically Induced Dynamic Nuclear Polarization
CONOSY	Combined COSY/NOESY
COLOC	Correlated Spectroscopy via Long-Range Coupling
COSY	Correlated Spectroscopy
COSY-45	COSY with 45° mixing pulse
COSYDEC	COSY with F ₂ Decoupling
COSYLR	COSY for Long-Range couplings
CP	Cross Polarization
CPD	Composite-Pulse Decoupling
CPMAS	Cross Polarization Magic-Angle Spinning
CPMG	Can-Purcell-Meiboom-Gill Sequence
CRAMPS	Combined Rotational and Multiple Pulse Spectroscopy
CRAZED	Correlated Spectroscopy Revamped by Asymmetric Z-gradient Echo Detection
CSA	Chemical Shift Anisotropy
CSCM	Chemical Shift Correlation Map
CSI	Chemical Shift Imaging
CT	Constant Time
CW	Continuous Wave
CYCLCROP	Cyclic Cross Polarization
CYCLOPS	Cyclically Ordered Phase Sequence
CYCLPOT	Cyclic Polarization Transfer
DAC	Digital-to-Analog Converter
DANTE	Delay Alternating with Nutation for Tailored Excitation
DAS	Dynamic Angle Spinning
DCNMR	NMR in Presence of an Electric Direct Current
DD	Dipole-Dipole
DECSY	Double-quantum Echo Correlated Spectroscopy
DEFT	Driven Equilibrium Fourier Transform
DEPT	Distortionless Enhancement by Polarization Transfer
DEPTH	spin-echo sequence for spatial localization
DFT	Discrete Fourier Transformation
DIGGER	Discrete Isolation from Gradient-Governed Elimination of Resonances
DIPSI	Composite-pulse Decoupling in the presence of scalar interactions
DISCO	Differences and Sums within COSY
DLB	Differential Line Broadening
DNMR	Dynamic NMR
DNP	Dynamic Nuclear Polarization
DOPT	Dipolar Order Polarization Transfer
DOR	Double-Orientation Rotation

(Continued)

Appendix 19. (Continued)

Abbreviations and Acronyms Used in Magnetic Resonance

DOUBTFUL	Double Quantum Transition for Finding Unresolved Lines	GRECCO	Gradient-Enhanced Carbon Coupling
DQ	Double Quantum	GROESY	Gradient-Enhanced Selective 1D ROESY
DQC	Double Quantum Coherence	GROPE	Generalized compensation for Resonance Offset and Pulse length errors
DQF	Double Quantum Filter	GS	Gradient Spectroscopy
DQF-COSY	Double Quantum Filtered COSY	H,X-COSY	X-detected heteronuclear cosy
DQSY	Double-Quantum COSY	HETCOR	Heteronuclear Correlation Spectroscopy
DQ/ZQ	Double Quantum/Zero Quantum Spectroscopy	HEHAHA	Heteronuclear Hartmann Hahn
DRESS	Depth Resolved Spectroscopy	HMBC	Heteronuclear Multiple-Bond Correlation
DSA	Data-Shift Acquisition	HMQ	Heteronuclear Multiple-Quantum
E.COSY	Exclusive Correlation Spectroscopy	HMQC	Heteronuclear Multiple-Quantum Coherence
EFG	Electric Field Gradient	HNCO	¹H-detected 3D correlation for peptide bonds
EHT	Extended Hückel Molecular Orbital Theory	HOESY	Heteronuclear Overhauser Effect Spectroscopy
ELD	Energy Level Diagram	HOHAHA	Homonuclear Hartmann Hahn Spectroscopy
ENDOR	Electron-Nuclear Double Resonance	HR	High Resolution
ENMR	Electrophoretic NMR	HRPA	Higher Random Phase Approximation
EOM	Equations of Motion	HSQC	Heteronuclear Single-Quantum Coherence
EPI	Echo Planar Imaging	IDESS	Improved Depth Selective single surface coil Spectroscopy
ESR	Electron Spin Resonance	IGLO	Individual Gauge for different Localized Orbitals
EXORCYCLE	4-step phase cycle for spin echoes	INADEQUATE	Incredible Natural Abundance Double Quantum Transfer Experiment
EXSY	Exchange Spectroscopy	INDO	Intermediate Neglect of Differential Overlap
FC	Fermi Contact or Field Cycling	INDOR	Intruclear Double Resonance
FFT	Fast Fourier Transform	INDO/S	Intermediate Neglect of Differential Overlap Calculations for Spectroscopy
FID	Free Induction Decay	INEPT	Insensitive Nuclei Enhanced by Polarization
FIDS	Fitting of Doublets and Singlets	INVERSE	H, X correlation via ¹H detection
FRFT	Fast Inversion-Recovery Fourier Transform	IR	Inversion-Recovery
FLASH	Fast Low-angle Shot imaging	ISIS	Image-Selected in vivo Spectroscopy
FLOPSY	Flip-Flop Spectroscopy	IST	Irreducible Spherical Tensor
FOCSY	Foldover-Corrected Spectroscopy	JCP	J Cross-Polarization
FOV	Field of View	JR	Jump-and-Return sequence (90, -t-90)
FPT	Finite Perturbation Theory	LAS	Laboratory Axis System
FT	Fourier Transform	LIS	Lanthanide Induced Shift
FUCOUP	Fully Coupled Spectroscopy	LORG	Local Origin
FWHM	Full (line) Width at Half Maximum	LOSY	Localized Spectroscopy
GARP	Globally Optimized Alternating Phase Rectangular Pulses	LP	Linear Prediction
GE	Gradient Echo	LSR	Lanthanide Shift Reagent
GES	Gradient-Echo Spectroscopy		
GIAO	Gauge Included Atomic Orbitals		
GRASS	Gradient-Recalled Acquisition in the Steady State		
GRASP	Gradient-Accelerated Spectroscopy		

(Continued)

Appendix 19. (Continued)

Abbreviations and Acronyms Used in Magnetic Resonance

MAGROFI	Magnetization Grid Rotating-Frame Imaging	PSD	Phase-sensitive Detection
MARF	Magic Angle in the Rotating Frame	PW	Pulse Width
MAS	Magic-Angle Spinning	QF	Quadrupole moment/Field gradient (interaction or relaxation mechanism)
MASS	Magic-Angle Sample Spinning	QPD	Quadrature Phase Detection
MEDUSA	Technique for the Determination of Dynamic Structures	RARE	Rapid Acquisition Relaxation Enhanced
MEM	Maximum Entropy Method	RCT	Relayed Coherence Transfer
MINDO	Modified INDO	RE-BURP	Refocused Band-selective Uniform Response Pure phase
MLEV	M. Levitt's CPD sequence	RECSY	Multistep Relayed Coherence Spectroscopy
MP	Multiple-Pulse	REDOR	Rotational Echo Double Resonance
MQ	Multiple-Quantum	RELAY	Relayed Correlation Spectroscopy
MQC	Multiple-Quantum Coherence	REX	Relativistically Extended Hückel molecular orbital theory
MQF	Multiple-Quantum Filter	RF	Radio Frequency
MQS	Multiple-Quantum Spectroscopy	RIDE	Ring Down Elimination
MREV	Mansfield-Rhims-Ellman-Vaughan sequence for dipolar line narrowing	RODI	Rotating-frame relaxation Dispersion Imaging
MRI	Magnetic Resonance Imaging	ROESY	Rotating-Frame Overhauser Effect Spectroscopy
MRS	Magnetic Resonance Spectroscopy	ROTO	ROESY-TOCSY Relay
MRSI	Magnetic Resonance Spectroscopic Imaging	RPA	Random Phase Approximation
MRT	Magnetic Resonance Tomography	SA	Shielding Anisotropy
MSPGSE	Multiple-Stepped PGSE	SC	Scalar Coupling
NERO	Nonlinear Excitation with Rejection on Resonance	SCPT	Self-Consistent Perturbation Theory
NMR	Nuclear Magnetic Resonance	SD	Spin Dipolar
NOE	Nuclear Overhauser Effect	SDDS	Spin Decoupling Difference Spectroscopy
NOESY	Nuclear Overhauser Effect Spectroscopy	SE	Spin Echo
NOCC	Nuclear Quadrupole Coupling Constant	SECSY	Spin-Echo Correlated Spectroscopy
NQR	Nuclear Quadrupole Resonance	SEDOR	Spin-Echo Double Resonance
ODMR	Optically Detected Magnetic Resonance	SEDUCE	Selective Decoupling Using Crafted Excitation
OSIRIS	modification of ISIS	SEFT	Spin-Echo Fourier Transform Spectroscopy (with J modulation)
PAR	Phase-alternated Rotation of magnetization	SELINCOR	Selective Inverse Correlation
PAS	Principal Axis System	SELINQUATE	Selective INADEQUATE
PCOSY	Purged COSY	SELRESOLV	Selective Resolution of C-H Coupling
PE-COSY	Primitive E. COSY	SEMUT	Subspectral Editing Using a Multiple-Quantum Trap
PENDANT	Polarization Enhancement During Attached Nucleus Testing	SERF	Selective Refocussing
PFG	Pulsed Field Gradient	SESAM	Semi-Selective Acquisition Modulated (Decoupling)
PGSE	Pulsed Gradient Spin Echo		
PMFG	Pulsed Magnetic Field Gradient		
POF	Product Operator Formalism		
PRE	Proton Relaxation Enhancement		
PRESS	Point-Resolved Spectroscopy		
PRFT	Partially Relaxed Fourier Transform		

(Continued)

Appendix 19. (Continued)

Abbreviations and Acronyms Used in Magnetic Resonance

SFORD	Single Frequency Off-Resonance Decoupling
SGSE	Steady-Gradient Spin-Echo
SKEWSY	Skewed Exchange Spectroscopy
SL	Spin-Lock pulse
SLITDRESS	Slice interleaved Depth Resolved Surface coil Spectroscopy
SLOPT	Spin-Locking Polarization Transfer
SNR or S/N	Signal-to-Noise Ratio
SOPPA	Second-Order Polarization Propagator Approach
SPACE	Spatial and Chemical-Shift Encoded Excitation
SPI	Selective Population Inversion
SPT	Selective Population Transfer
SQC	Single-Quantum Coherence
SQF	Single-Quantum Filter
SR	Saturation-Recovery
SSFP	Steady-State Free Precession
SSI	Solid State Imaging
STE	Simulated Echo
STEAM	Simulated Echo Acquisition Mode for imaging
TANGO	Testing for Adjacent Nuclei with a Gyration Operator
TART	Tip Angle Reduced T ₁ imaging
TCF	Time Correlation Function
TE	Time delay between excitation and Echo maximum
TMR	Topical Magnetic Resonance
TOCSY	Total Correlation Spectroscopy
TOE	Truncated NOE
TORO	TOCSY-ROESY Relay
TOSS	Total Suppression of Sidebands
TPPI	Time-proportional Phase Incrementation
TQ	Triple-Quantum
TQF	Triple-Quantum Filter
TR	Time for Repetition of excitation
TRCF	Tilted Rotating Coordinate Frame
TROSY	Transverse Relaxation optimized Spectroscopy
TSETSE	Double resonance two-spin effect

[illegible]

Appendix 20. Symbols used in magnetic resonance

B	Magnetic flux density
B_{loc}	Local magnetic flux density contribution by secular interaction
B_0	Stationary main magnetic flux density in z direction
η	Asymmetry parameter (or anisotropy constant) or nuclear Overhauser enhancement factor
δ	Chemical shift (ppm)
G	Gradient of the main magnetic flux density
γ_n	Gyromagnetic ratio of nucleus n
I	Spin quantum number
J	(Indirect) spin–spin coupling constant (in Hz)
M	Magnetization in the laboratory frame
M'_x, M'_y, M'_z	Magnetization components in the rotating frame along the x' , y' , and z' axes, respectively
M_0	Equilibrium (Curie) magnetization
μ	Magnetic dipole moment
μ_0	Magnetic field constant
μ_B	Bohr magneton
μ_N	Nuclear magneton
ω_L	Larmor (angular) frequency
ω_m	Modulation angular frequency (in rad s^{-1})
ω_0	Larmor or resonance (angular) frequency
ω_r	Sample rotation frequency (rad s^{-1})
ω_L	Larmor (angular) frequency in B_1
Q	Nuclear quadrupole moment
P	Density operator
R_1	Spin–lattice relaxation rate
R_2	Transverse relaxation rate
R_{IS}	Cross-relaxation rate
σ	Chemical shift shielding tensor
T_1	Longitudinal (spin–lattice) relaxation time for M_z
T_2	Transverse (spin–spin) relaxation time for M_{xy}
T_2^*	Time constant of the FID in the presence of B_0 inhomogeneities
T_{2e}	Transverse relaxation time effective under multiple-pulse irradiation
T_{2p}	Transverse relaxation time during a spin-lock pulse
t_1, t_2	Time domains in multidimensional experiments
T_{1p}	T_1 of spin-locked magn. in rotation frame
T_{2p}	T_2 of spin-locked magn. in rotation frame
T_E, t_e	Echo time
t_n	Time domain of the n th dimension
F_n	Frequency domain of the n th dimension
t_m	Mixing time
T_R, t_r	Repetition time
τ_c	Correlation time
τ_{coll}	Mean time between molecular collision in the liquid state
τ_j	Angular momentum correlation time
$\tau, \tau_1, \tau_2, \dots$	Intervals in pulse sequences
W_0, W_1, W_2	Transition probabilities for zero-, single-, and double-quantum transitions
Ω	Frequency offset
χ	Magnetic susceptibility
$Y_{l,m}$	Spherical harmonics

Appendix 21. EPR/ENDOR frequency table

revision 2006 based on NMR Properties Table, W. E. Hull; no. of decimal places reflects precision.

Appendix 22. Some useful conversion factors in EPR

1) To obtain the magnetic field B of a resonance line in Tesla, the klystron frequency ν_e expressed in GHz is multiplied by the factor 0.071 447 75 and divided by the g factor, and 2) a hyperfine coupling constant A expressed in the units cm^{-1} is multiplied by $2.99\,792\,46 \times 10^4$ to convert it to MHz.

$\begin{aligned}\nu_e \text{ (GHz)} &= 13.996\,2\,g\,B \text{ (T)} \\ &= 1.39962\,g\,B \text{ (kG)}\end{aligned}$	$\begin{aligned}A \text{ (MHz)} &= 2.997\,924\,6 \times 10^4 A \text{ (cm}^{-1}\text{)} \\ &= 13.9962\,g\,A \text{ (mT)} \\ &= 1.399\,62\,g\,A \text{ (G)}\end{aligned}$
$B \text{ (T)} = \frac{0.071\,447\,75}{g} \nu_e \text{ (GHz)}$	$\begin{aligned}A \text{ (cm}^{-1}\text{)} &= 0.333\,564\,10 \times 10^{-4} A \text{ (MHz)} \\ &= 4.668\,63 \times 10^{-4} g\,A \text{ (mT)}\end{aligned}$
$\nu_p \text{ (MHz)} = 42.576\,38\,B \text{ (T)} \quad (\text{H}_2\text{O})$	$1 \text{ mT} = 10 \text{ G}$
$B \text{ (T)} = 0.023\,487\,20\,\nu_p \text{ (MHz)} \quad (\text{H}_2\text{O})$	
$\begin{aligned}g &= 0.071\,447\,75 \frac{\nu_e \text{ (GHz)}}{B \text{ (T)}} \\ &= 3.041\,987 \frac{\nu_e \text{ (GHz)}}{\nu_p \text{ (MHz)}}\end{aligned}$	

Appendix 23. MS: Exact masses of the isotopes

Atomic Masses and Representative Abundances of the Isotopes (NIST)

The masses and abundances of the isotopes we use for generating molecular formulas, simulating patterns and SNAP peak finding basically are taken from the National Institute of Standards and Technology (NIST).

Z = Atomic number, M = mass number; Abund. = isotope abundance.

Appendix 23. (Continued)

Atomic Masses and Representative Abundances of the Isotopes (NIST)

The masses and abundances of the isotopes we use for generating molecular formulas, simulating patterns and SNAP peak finding basically are taken from the National Institute of Standards and Technology (NIST).

Z = Atomic number, M = mass number; Abund. = isotope abundance.

Z	E	M	Exact Mass	Abund.	Valency	Z	E	M	Exact Mass	Abund.	Valency

Originally published as: IUPAC, Atomic Weights of the Elements 1993, Pure Appl. Chem. 73(4), 687 (2002); K.J.R. Rosman and P.D.P. Taylor, Isotopic Compositions of the Elements 1993, J. Phys. Chem. Ref. Data 27(6), 1275 (1998); and G. Audi and A.H. Wapstra, The 1993 Update to The Atomic Mass Evaluation, Nuclear Physics A 695(4), 409 (1999)

The following modifications/additions were made to the NIST Atomic Weights and Isotopic Compositions (version 2.3.1) table:

- Uu was renamed to Oganessonium which is now the official name.
- Additional elements C, Ir and O were defined which have an abundance of 95% of 12C, 10% and 18O and 5% of 12C, 14C and 16O. These elements were added to calculate isotopically weighted substances.
- The valencies of the atoms are listed additionally. For quickly inspecting the valencies listed, please refer to the Table of Valencies.

 The following modifications/additions were made to the NIST Atomic Weights and Isotopic Compositions (version 2.3.11) table:
 • Unit was changed to Da (Dalton) which is now the official name.
 • Additional values for Os, Ir, Pt, Au, Hg, Pb, Bi, Th, Pa, U, and Pu were defined which take an abundance of 99% of 13C, 100% and 180% of 12C, 100% and 100%. These elements were added to calculate isotopically marked substrates.
 • The abundance of the elements are listed additionally for quickly inspecting the elements used, please refer to the Table of Valencies.

Appendix 29. Physical tables

Fundamental Physical Constants (CODATA 2006) *

Quantity	Symbol	SI Value
Speed of Light (vacuum)	c, c_0	299 792 458 m s ⁻¹ (defined)
Permeability of vacuum	μ_0	4 π × 10 ⁻⁷ H m ⁻¹ or N A ⁻² (defined)
Permittivity of vacuum	$\epsilon_0 = 1/(\mu_0 c^2)$	8.854 187 817 × 10 ⁻¹² F m ⁻¹ (defined)
Planck Constant	h $\hbar = h/2\pi$ (au)	6.626 068 96 (33) × 10 ⁻³⁴ J s 1.054 571 628 (53) × 10 ⁻³⁴ J s
Elementary Charge (au)	e	1.602 176 487 (40) × 10 ⁻¹⁹ C
Electron Rest Mass (au)	m_e	9.109 38215 (45) × 10 ⁻³¹ kg
Proton Rest Mass	m_p	1.672 621 637 (83) × 10 ⁻²⁷ kg
Proton/Electron Mass Ratio	m_p/m_e	1836.152 672 47 (80)
Neutron Rest Mass	m_n	1.674 927 211 (84) × 10 ⁻²⁷ kg
Deuteron Rest Mass	m_d	3.343 583 20 (17) × 10 ⁻²⁷ kg
Atomic Mass Unit (¹² C/12)	$m_u = 1\text{ u} = 1\text{ Da}$	1.660 538 782 (83) × 10 ⁻²⁷ kg
Avogadro's Number	N_A	6.022 141 79 (30) × 10 ²³ mol ⁻¹
Boltzmann Constant	k	1.380 6504 (24) × 10 ⁻²³ J K ⁻¹
Faraday Constant	F	96 485 3399 (24) × 10 ⁴ C mol ⁻¹
Gas Constant	R	8.314 472 (15) J mol ⁻¹ K ⁻¹
Molar Volume of ideal gas ^b	$V_m = RT/p$	22.413 996 (39) × 10 ⁻³ m ³ mol ⁻¹
Standard Atmosphere	atm	101.325 kPa (defined)
Fine Structure Constant	$\alpha = \mu_0 e^2 c_0 / 2h$	7.297 352 5376 (50) × 10 ⁻³
Inverse Fine-Structure Constant	$1/\alpha$	137.035 999 679 (94)
Bohr Radius (au)	$a_0 = 4\pi\epsilon_0 \hbar^2 / m_e e^2$	0.529 177 208 59 (36) × 10 ⁻¹⁰ m
Hartree Energy (au)	$E_h = \hbar^2 / m_e a_0^2$	4.359 743 94 (22) × 10 ⁻¹⁸ J
Rydberg Constant	$R_\infty = E_h / 2hc_0$	10 973 731.568 527 (73) × 10 ¹ m ⁻¹
Compton Wavelength (Electron)	$\lambda_C = h / m_e c_0$	2.426 310 2175 (33) × 10 ⁻¹² m
Bohr Magneton (β_B)	$\mu_B = e\hbar / 2m_e$	927.400 915 (23) × 10 ⁻²⁴ J T ⁻¹
Electron Magnetic Moment	μ_e	-928.476 377 (23) × 10 ⁻²⁴ J T ⁻¹
Electron Magnetogyric Ratio	$\gamma_e = 2\mu_e / \hbar$ $\gamma_e / 2\pi$	1.760 859 770 (44) × 10 ¹¹ s ⁻¹ T ⁻¹ 28.024 953 64 (70) GHz T ⁻¹
Free Electron Landé g factor	$g_e = 2\mu_B / \mu_e$	-2.002 319 304 3718 (75)
Nuclear Magneton (β_N)	$\mu_N = (m_e / m_p) \mu_B$	5.050 783 24 (13) × 10 ⁻²⁷ J T ⁻¹
Proton Magnetic Moment (free)	μ_p	1.410 606 662 (37) × 10 ⁻²⁶ J T ⁻¹
(shielded, H ₂ O sphere, 25°C)	μ_p'	1.410 570 419 (38) × 10 ⁻²⁶ J T ⁻¹
Proton Magnetogyric Ratio (free)	γ_p	2.675 222 099 (70) × 10 ⁸ s ⁻¹ T ⁻¹
(shielded, H ₂ O sphere, 25°C)	γ_p'	2.675 153 362 (73) × 10 ⁸ s ⁻¹ T ⁻¹
Proton MR freq. in H ₂ O	$\gamma_p' / 2\pi$	42 576 3881 (12) MHz T ⁻¹
Electron/Proton Magn. Mom. Ratio	μ_e / μ_p	-658.210 6848 (54)
Deuteron Magnetic Moment	μ_d	0.433 073 465 (11) × 10 ⁻²⁶ J T ⁻¹
Gravitation Constant (Newtonian)	G	6.674 28 (67) × 10 ⁻¹¹ m ³ kg ⁻¹ s ⁻²
Standard Acceleration (Earth gravity)	g	9.806 65 m s ⁻² (defined)
$\pi = 3.141 592 653 59$	$e = 2.718 281 828 46$	$\ln 10 = 2.302 585 092 99$

^b at STP of 273.15 K and 101.325 kPa = 1 atm.

Subject Index

Notes

Cross-reference terms in italics are general cross-references, or refer to subentry terms within the main entry (the main entry is not repeated to save space). Readers are also advised to refer to the end of each article for additional cross-references - not all of these cross-references have been included in the index cross-references.

The index is arranged in set-out style with a maximum of three levels of heading. Major discussion of a subject is indicated by bold page numbers. Page numbers suffixed by T and F refer to Tables and Figures respectively. vs. indicates a comparison.

This index is in letter-by-letter order, whereby hyphens and spaces within index headings are ignored in the alphabetization. Prefixes and terms in parentheses are excluded from the initial alphabetization.

Where index subentries and sub-subentries pertaining to a subject have the same page number, they have been listed to indicate the comprehensiveness of the text.

A

absorption

basic concepts, **268–283**

absolute configuration rules

chirality functions, 277–278, 278*F*

exciton chirality method, 280–283, 280*F*, 281*F*, 283*F*

helicity rules, 279–280, 280*F*

sector rules, 278–279, 278*F*, 279*F*, 280*F*

chromophores

characteristics, 274–275

enone chromophore, 273–274, 274*F*, 280*F*

molecular decomposition effects, 275*F*

classifications, 273–274

isotropic media, 270–272

optical rotary dispersion (ORD), 270–272, 271*F*, 2916–2920

oriented molecules, 269–270

polarized absorption, 272*F*

rotational strength

general discussion, 275

model of independent groups (MIG)

calculation method, 276–277

one-electron mechanism, 276

polarizability theory, 275–276

quantum mechanical calculations, 275

vibrational progressions, 272–273, 273*F*

accelerator mass spectrometry (AMS), 1–3

characteristics, 1

instrumentation, 1–2

isotopic labelling, 2–3, 3*T*, 1240–1242, 1241*F*

sample preparation/presentation, 2

accurate mass and time (AMT) tag

proteomics, 2282, 2283*F*

acetaldehyde, 1694*F*

acetamide, 131–135*T*

acetanilide, 1197*F*

acetate

hydrogen-1 magnetic resonance

spectroscopy (¹H NMR)

biofluid analyses, 131–135*T*

in vivo magnetic resonance spectroscopy, 1079, 2061*F*

in vivo magnetic resonance spectroscopy

carbon-13 magnetic resonance

spectroscopy (¹³C NMR), 218*F*

hydrogen-1 magnetic resonance

spectroscopy (¹H NMR), 1079,

2061*F*

acetic acid, 2525*F*, 2847*T*

acetoacetate, 131–135*T*

acetone

chromophore energy transitions, 247*T*

Raman spectra, 1012*F*

selected-ion flow tube (SIFT) analysis,

2524*F*, 2526*F*, 2528*F*, 2529

tin-119 nuclear magnetic resonance (¹¹⁹Sn NMR) spectroscopy, 802*F*

acetonitrile, 802*F*, 858*F*, 2034*T*, 2847*T*

acetylacetonates, 2049*F*

N-acetylaspatic, 218*F*

acetylcarnitine, 1491*T*

acetylene (C₂H₂)

chemical shift parameters, 362*T*

interstellar and circumstellar molecules, 1070*T*

ionization cross sections, 1468*F*

molecular geometry determinations,

878–879, 878*T*

acetyltryptophan, 1486*T*

acetyltyrosine, 1486*T*, 1488–1489, 1490*F*

acoustically-induced nuclear relaxation, 2614, 2614*F*

acoustic nuclear magnetic resonance

(ANMR), 2613

acousto-optic tunable filters (AOTFs), 2351–2352

acridine orange, 636*T*

acrylonitrile, 1249–1252, 1251*F*, 1252*F*

acyclic polyols/aminopolyols, 550–551, 551*F*

acyl chloride, 362*T*

acyl-CoA dehydrogenase deficiencies, 1489–1493, 1491*F*

acyl phosphates, 2211*T*

adamantane (C₁₀H₁₆), 457*F*, 461*F*, 859–860, 859*F*

adenine

characteristics, 1984

fluorescence spectroscopic analyses, 2044

molecular structure, 167*F*, 1732*F*, 1985*F*

nitrogen-15 (¹⁵N) chemical shift tensors, 1895*T*

ultraviolet (UV) spectrum, 167*F*

adenosine, 1992, 1993*F*, 2044

adenosine diphosphate (ADP), 215–216, 1114, 2100–2101

adenosine triphosphate (ATP), 215–216,

1113, 1113*F*, 2100–2101, 2102*F*

adiabatic capture centrifugal sudden approximation (ACCSA), 1120–1121

adipate, 131–135*T*

adipic acid, 1486*T*

adipose tissue, 1102

adipylcarnitine, 1491*T*

aequorin, 113–114

agricultural studies

atomic spectroscopic analyses, **494–501**

air and dust analyses, 500

general discussion, 494–495

plant materials, 500–501, 500*F*

soil analyses, 498–499

water analyses, 499–500, 499*F*

- air and dust analyses
 agricultural studies, 500
 forestry and wood products research, 708
 Airy formula, 477
 Alamar blue, 636*T*, 640, 641*T*, 642*F*, 643*F*
 alanine
 cell research, 217*F*, 218*F*
 hydrogen-1 magnetic resonance spectroscopy (^1H NMR)
 biofluid analyses, 131–135*T*
 in vivo magnetic resonance spectroscopy, 1079, 1110*F*, 2060*F*, 2061*F*
 tissue extract analyses, 926*F*
 in vivo magnetic resonance spectroscopy
 carbon-13 magnetic resonance spectroscopy (^{13}C NMR), 217*F*, 218*F*, 1100–1101
 hydrogen-1 magnetic resonance spectroscopy (^1H NMR), 1079, 1110*F*, 2060*F*, 2061*F*
 labelled material studies, 1253

canola oil, 678 *T*
canonical analysis, 1518 *F*
canonical rate constant, 1129
CantiClever concept design, 1424–1425,
1424 *F*
capillary electrochromatography (CEC),
1879–1880, 2643 *F*
capillary electrophoresis (CE)
biomedical applications, 112
environmental applications, 507, 507 *F*
metabonomic studies, 1666
nuclear magnetic resonance (NMR)
spectroscopy, 1879–1880
pharmaceutical research and development,
2643 *F*
plant science analyses, 2186
capillary zone electrophoresis (CZE), 315,
985
capric acid, 1486 *T*
carbamates, 1791 *F*
carbene radical reactions, 323, 1760*F*, 1764 *T*
carbodiimides, 1791 *F*
carbohydrates
circular dichroism (CD) spectroscopy
conformational transition analyses,
163–165, 165 *F*
general discussion, 162–163
structure determinations, 163, 164 *F*
vibrational circular dichroism (VCD),
2893–2894
nuclear magnetic resonance (NMR)
spectroscopy, 204–211
carbon-13 magnetic resonance
spectroscopy (^{13}C NMR)
carbon–proton/carbon–carbon spin
couplings, 209
multidimensional heteronuclear
analysis, 209, 210 *F*
primary analysis and assignment, 209
complex carbohydrate identification, 211
conformational analyses, 209–211, 210 *F*
dynamic processes, 211
general discussion, 204
hydrogen-1 magnetic resonance
spectroscopy (^1H NMR)
hydroxyl protons, 208–209
primary analysis and assignment,
205–206, 205*F*, 206 *F*
structural reporter groups, 206 *T*
two-dimensional (2D) homonuclear
analysis, 206–207
sample preparation, 204–205
structural analyses, 205, 205 *F*
two-dimensional (2D) homonuclear
analysis
COSY-type experiments, 207, 207 *F*
general discussion, 206–207
homonuclear Hartmann–Hahn
(HOHAHA) experiments, 208
multiple quantum experiments, 208
nuclear Overhauser enhancement
spectroscopy (NOESY), 208
RELAY experiments, 208
rotating frame Overhauser effect
spectroscopy (ROESY), 208
TOCSY-type experiments, 208
proton affinities, 2847 *T*
Raman optical activity (ROA)
measurements, 2361–2362, 2369,
2383–2384
ultraviolet visible (UV-Vis) spectroscopic
analyses, 168
carbonaceous chondrites, 415, 416 *F*
carbon (C)
accelerator mass spectrometry (AMS),
2–3, 3 *T*
atomic mass, 1453 *T*
bulk biomedical concentrations, 174 *T*
carbon-11 (^{11}C)-flumazenil (FMZ), 2247
carbon-11 (^{11}C)-raclopride, 2247
carbon-13 magnetic resonance spectroscopy
(^{13}C NMR)
analytical methods, 355–364
attached-proton test (APT), 358–360,
358*F*, 359 *F*
chemical shift experiments, 361–363,
361*F*, 362 *T*, 363 *T*
distortionless enhancement by
polarization transfer (DEPT) test,
359, 359*F*, 360 *F*
general discussion, 355
heteronuclear decoupling, 356–357,
357 *F*
insensitive nuclei enhanced by
polarization transfer (INEPT)
test, 360
multiple pulse experiments, 358–360
nuclear Overhauser effect (NOE),
357–358, 358 *T*
single-pulse Fourier transform NMR,
355–356, 356 *F*
spectral assignment tests, 361–363
structural determinations, 361–363
two-dimensional nuclear magnetic
resonance (2D NMR)
spectroscopy, 360–361, 360 *T*,
361 *F*

 product operator formalism, 2270–2271
 spectral editing pulse sequences, 1847, 1848*F*
 8,9-disubstituted-tricyclo[5.2.1.0^{2,6}] decenes, 603*F*, 604*F*, 605–606
 DNA-binding molecule analyses
 binding site analyses, 1000–1001
 chiral conformational studies, 1002–1004, 1003*F*
 general discussion, 1000
 groove-bound and intercalator ligand–DNA complex geometries, 1001–1002, 1001*F*, 1002*F*, 1002*T*, 1003*F*
 Pfeiffer effect, 1003*F*
 structural analyses
 induced circular dichroism (ICD), 1001, 1001*F*, 1002*T*
 nuclear magnetic resonance (NMR) spectroscopy, 2751–2753, 2751*F*, 2752*F*, 2753*F*, 2754*F*
 DNA nucleotide studies, 2479, 2479*F*

- dogfish muscle and liver analyses, 657–659 *T*
Doppler broadening parameters, 64–65
Doppler-free two-photon spectroscopy, 1274–1275, 1276 *F*
double-focusing mass spectrometer, 421, 421 *F*, 2507–2508
double-quantum filtered correlation (DQF–COSY), 2269, 2745–2746, 2747 *F*
double-resonance multiphoton spectroscopy, 1699–1700, 1700 *F*
double-resonance spectroscopy, 1275–1277, 1277 *F*
double-rotation (DOR) experiments, 835–836, 1830–1832, 2584–2586, 2588–2589
Drucaena cinnabari, 736, 737 *F*
dragon's blood, 25, 736, 737 *F*
DRAMA (dipolar recovery at the magic angle), 2602 *T*
DRAWS (dipolar recoupling with a windowless multipulse irradiation), 2602 *T*
drift tube IMS (DTIMS), 1141–1143, 1142 *F*
driving impairment, 695–696
drug metabolism analyses
 metabonomics, 2067
 nuclear magnetic resonance (NMR)
 spectroscopy, 429–441
 advantages/disadvantages
 in vitro research, 431–432, 431 *T*
 in vivo research, 432–433, 433 *T*
 boron-11 magnetic resonance spectroscopy (^{11}B NMR), 429 *T*, 430–431
 carbon-13 magnetic resonance spectroscopy (^{13}C NMR)
 characteristics, 429 *T*, 430
 recent research, 436, 438 *F*
 in vivo research, 438 *F*
 fluorine-19 magnetic resonance spectroscopy (^{19}F NMR)
 characteristics, 429, 429 *T*
 recent research, 433–439, 434 *F*, 435 *F*, 436 *F*
 in vitro research, 431–432
 in vivo research, 433–439, 436 *F*
 hydrogen-1 magnetic resonance spectroscopy (^1H NMR)
 characteristics, 429 *T*, 430
 recent research, 436, 437 *F*
 in vitro research, 431–432
 hydrogen-2 magnetic resonance spectroscopy (^2H NMR), 429 *T*, 431
 lithium-7 magnetic resonance spectroscopy (^7Li NMR), 429 *T*, 430, 438–439
 nitrogen-14 nuclear magnetic spectroscopy (^{14}N NMR), 429 *T*, 431
 nitrogen-15 nuclear magnetic spectroscopy (^{15}N NMR), 429 *T*, 431
 oxygen-17 magnetic resonance spectroscopy (^{17}O NMR), 429 *T*, 431
 phosphorus-31 magnetic resonance spectroscopy (^{31}P NMR)
 characteristics, 429 *T*, 430
 recent research, 438, 439 *F*, 440 *F*
 platinum-195 magnetic resonance (^{195}Pt NMR) spectroscopy, 429 *T*, 431
 drug quality control, 2640–2650
 background information, 2640
 characterization analyses, 2128
 drug development process
 background information, 2132
 clinical (IND) phases, 2133 *T*, 2134–2135
 metal-containing compounds, 2135 *T*
 new drug application (NDA) phase, 2133 *T*, 2135–2136
 preclinical (discovery) phase, 2132–2134, 2133 *T*, 2134 *F*
 nuclear magnetic resonance (NMR)
 spectroscopy/mass spectrometry (MS) analyses
 background information, 2643–2644
 biomolecular analyses, 2644
 component-based structural elucidation, 2645–2646

light pipe GC–IR, 305, 305*F*

matrix isolation GC–IR, 305–306, 305*F*

matrix-isolation (MI) approach, 300–301, 300*F*

petrochemical applications, 298

polymer analyses, 300

subambient solute trapping (direct-deposition) approach, 300

subambient solute trapping GC–IR, 305, 305*F*

high-performance liquid

chromatography–Fourier transform

infrared (HPLC–FTIR) spectroscopy

flowcell approach, 301

solvent-elimination approach, 301

historical background, 2943–2944

hyphenated techniques, 987–988

industrial applications, 1014, 1014*F*, 1015*F*, 1016*F*

instrumentation, 615*F*, 2944

liquid chromatography–Fourier transform

infrared (LC–FTIR) spectroscopy

flow cell LC–IR, 306, 306*F*

general discussion, 306

interface characteristics, 308

interface diagrams, 306*F*

microbore LC–IR, 307

mobile phase elimination LC–IR, 306–307, 306*F*

photoacoustic spectroscopy (PAS) analyses, 2138

spectrometers, **1199–1209**

background information, 1199

basic optics, 1200*F*

commercial instrumentation, 1208–1209

cosine waves, 1200*F*

detectors, 1206–1207, 1207*F*, 1207*T*

Fourier transform VCD spectrometers, 2900*F*, 2901–2903, 2903*F*

frequency range and resolution, 1201–1203, 1202*F*

general discussion, 1199–1200

infrared (IR) region, 1199, 1199*F*

interferograms

measurement techniques, 1202–1203, 1203*F*, 1204*F*

signal processing, 1203–1205, 1205*F*

optical arrangement, 1201*F*

polarization-division FT–VCD

spectrometers, 2903–2904, 2905*F*

scanning mechanisms, 1205–1206, 1205*F*, 1206*F*

single-beam spectra, 1201*F*

step-scan instruments, 1207–1208, 1208*F*

supercritical fluid chromatography–Fourier

transform infrared (SFC–FTIR)

spectroscopy, 301–302, 307

surface-induced dissociation (SID),

2778–2780, 2780*F*

surface studies, **2813–2821**

catalysis, 2820, 2820*F*

chemisorption

basic concepts, 2818–2820

carbon monoxide (CO), 2818*F*

ethene, 2819*F*, 2820*F*

general discussion, 2813

high-area, finely-divided, surfaces, 2813

low-area flat surfaces, 2813–2815, 2814*F*, 2815*F*

physical absorption

basic concepts, 2816–2817

cyclohexanes, 2817*F*

methane (CH₄), 2816*F*, 2817*F*

zeolite–hydroxyl groups, 2817*F*

surface characterization, 2815–2816, 2815*F*, 2816*F*

surface-enhanced Raman spectroscopy (SERS), 2820–2821

thin-layer chromatography–Fourier

transform infrared (TLC–FTIR)

spectroscopy, 302

diffuse reflectance TLC–IR, 307–308, 307*F*

general discussion, 307–308

photoacoustic TLC–IR, 308

solute transfer TLC–IR, 308

Fourier transform–ion-cyclotron resonance

(FT–ICR) instruments, 1448, 1448*F*

1450*F*, 1678–1679, 2090, 2091*F*

Fourier transform microwave spectrometers

(FTMWS), 1540

Fourier transform NMR spectroscopy

Fourier transform–pulsed-gradient spin-

echo (FT–PGSE) method, 424–425,

424*F*, 425–427, 426*F*

G-matrix Fourier transform (GFT) NMR, 1734–1736, 1735*F*

infrared (IR) spectroscopy, 691F
in vivo magnetic resonance spectroscopy
carbon-13 magnetic resonance spectroscopy (^{13}C NMR), 216–219, 217F, 218F, 1100–1101, 1101F
hydrogen-1 magnetic resonance spectroscopy (^1H NMR), 1079, 2061F
labelled material studies, 1253
plant science analyses, 2185F
Raman optical activity (ROA) measurements, 2362, 2384, 2395, 2395F
- glutamate
cell research, 217F, 218F
hydrogen-1 magnetic resonance spectroscopy (^1H NMR)
biofluid analyses, 131–135T
in vivo magnetic resonance spectroscopy, 1078–1079, 1109F
in vivo magnetic resonance spectroscopy
carbon-13 magnetic resonance spectroscopy (^{13}C NMR), 217F, 218F, 1101–1102
hydrogen-1 magnetic resonance spectroscopy (^1H NMR), 1078–1079, 1109F
labelled material studies, 1253
- glutamic acid, 1750T
- glutamine
cell research, 217F, 218F
- hydrogen-1 magnetic resonance spectroscopy (^1H NMR)
biofluid analyses, 131–135T
in vivo magnetic resonance spectroscopy, 1079, 1109F
in vivo magnetic resonance spectroscopy
carbon-13 magnetic resonance spectroscopy (^{13}C NMR), 217F, 218F, 1101–1102
hydrogen-1 magnetic resonance spectroscopy (^1H NMR), 1079, 1109F
nitrogen-15 nuclear magnetic resonance spectroscopy (^{15}N NMR), 1104, 1105F
(M–H) $^+$ species fragmentation, 1750T
plant science analyses, 2185F
- glutaric acid, 1486T
- glutathione (GSH)
in vivo hydrogen-1 magnetic resonance spectroscopy (^1H NMR), 1078
microspectrofluorimetric analyses, 641–642
- glycerol
chemical shift parameters, 366–368
fast atom bombardment spectra, 571F
hydrogen-1 magnetic resonance spectroscopy (^1H NMR), 131–135T
- glycogen metabolism, 217F, 926F, 1100–1101, 1101–1102, 1101F, 1253, 1254F
- glycolic acid, 1486T
- glycoproteins, 2371, 2374F
- glyoxylic oxime, 1486T
- G-matrix Fourier transform (GFT) NMR, 1734–1736, 1735F
- GOESY-type experiments, 2722, 2722F, 2732F
- goethite, 28T
- gold (Au)
anode materials, 2991T
atomic absorption spectrometry (AAS), 51T, 2129–2131T
dielectric constants, 2797T
gold-197 (^{197}Au), 815
gold chloride (Au_2Cl_6), 2049F
isomer shift, 1577F
nuclei characteristics, 1976T
pharmaceutical compounds, 2135T
sample dilution factors, 176T
spectral interferences, 175T
- Good Manufacturing Practice Regulations, 195
- gradient enhanced spectroscopy (GES), 2869
- Gram–Schmidt vector orthogonalization method, 304–305

characteristics, 957–958
concentration dependence, 958, 958*F*
deuterium chloride–dimethyl ether ($\text{DCl}-(\text{CH}_3)_2\text{O}$) spectra, 958*F*
energy of interaction, 959–960
isopropanol spectra, 957*F*
strong H–bond systems, 960–961, 960*F*
temperature dependence, 958
thermodynamic quantity estimation, 960
bulk biomedical concentrations, 174*T*
cosmic abundances, 414*F*
- deuterium (D)
electric discharge sources, 1335*T*
protein and peptide analyses, 2098
quadrupolar interactions, 1351*T*
reaction product ion imaging, 1561–1562, 1562*F*
- hydrochloric acid (HCl), 775*T*, 3042–3043
- hydrogen-1 magnetic resonance spectroscopy (^1H NMR)
biofluid analyses, 128–141
amniotic fluid, 129*T*, 139–140
aqueous humor, 129*T*, 140
background information, 128
bile, 129*T*, 139
blood serum and plasma, 129*T*, 130–136, 130*F*
cerebrospinal fluid (CSF), 129*T*, 138–139
digestive fluids, 140
dynamic interactions, 129–130
follicular fluid, 129*T*, 139–140
food and nutritional science, 1513–1514
metabolites, 131–135*T*
metabonomic studies, 1513–1514, 2058–2059, 2060*F*, 2061*F*, 2062*F*
milk, 129*T*, 140
pathologic cyst fluid, 140–141
resonance assignments, 129, 131–135*T*
saliva, 129*T*, 140
seminal fluids, 129*T*, 139
solvent suppression methods, 2604
spectral data, 130*F*
synovial fluid, 129*T*, 140
urine, 129*T*, 136–137
vitreous humor, 140
biomedical applications, 2099*T*, 2104, 1077–1084, 1107–1111
- carbohydrate analyses
hydroxyl protons, 208–209
primary analysis and assignment, 205–206, 205*F*, 206*F*

- structural reporter groups, 206 *T*
two-dimensional (2D) homonuclear analysis, 206–207
- cell research, 219–220, 219*F*, 220*F*
characteristics, 213 *T*, 429 *T*, 1816
chemically induced dynamic nuclear polarization (CIDNP)
biologically relevant molecules, 323–324
biradical reactions, 322–323
carbene radical reactions, 323
complex radical chemical reactions, 321–322
high magnetic field effects, 318–320, 319*F*
low magnetic field effects, 320–321
magnetic resonance parameters studies, 321–322, 322 *T*
molecular dynamics research, 323
multiplet effects, 318, 319*F*
net effects, 318, 319*F*
nuclei spin data, 318, 318 *T*
observation techniques, 318
spin dynamics research, 323
structural chemistry analyses, 321–322, 322*F*
technique comparisons, 321
- cross polarization (CP) analyses, 1829, 1831*F*, 2588
- drug metabolism analyses, 430, 431–432, 436, 437*F*
- drug quality control, 2644, 2647*F*, 2648*F*
- food and nutritional science
applications, 664–665, 678 *T*, 1513–1514, 1514*F*
- gas phase studies, 750*F*, 754, 754*F*
- high-power decoupling, 1828–1829, 1831*F*
- high-resolution NMR spectroscopy, **905–916**
abundant spin determination methods, 906–911, 911*F*
combined rotation and multiple-pulse spectroscopy (CRAMPS), 906–911, 911*F*
general discussion, 905
inorganic solids analyses, 913
lipid bilayer analyses, 914–915, 914*F*
liquid crystal analyses, 914–915
nuclear spin properties, 905–906, 906 *T*
organic molecule analyses, 913
oriented sample analyses, 913
peptides and proteins, 915
polymer and rubber analyses, 914
proton–proton (¹H–¹H) decoupling, 911–913, 912*F*
- in vivo* magnetic resonance spectroscopy, **1085–1098**
advanced techniques, 1095–1097
anomalous *J*-modulation, 1097
artifacts, 1097
chemical shift displacement, 1097
chemical shifts, 1086–1087, 1086*F*
flow and motion factors, 1098
ghosting, 1097
image selected *in vivo* spectroscopy (ISIS), 1089
J-coupled techniques, 1095–1097, 1096*F*
localization sequences, 1087–1090, 1089*F*, 1094*F*
magnetic resonance spectroscopic imaging (MRSI), 1093–1095, 1094*F*
methodology, 1087–1090
modulation sidebands, 1097
outer-volume suppression (OVS), 1090–1091, 1090*F*, 1094*F*
postprocessing/quantification methods, 1091–1093, 1092*F*, 1093*F*
relaxation behavior, 1087, 1088 *T*
sensitivity factors, 1087, 1088 *T*
shimming techniques, 1091
spectral resolution, 1086–1087
stimulated echo acquisition mode (STEAM), 1088, 1089*F*
stimulated echoes, 1098
three-dimensional (3D) localization by adiabatic selective refocusing (LASER), 1088–1089
labelled material studies, 1247
liquid crystals
molecular dynamics research, 1354–1355
orientational order parameters, 1353–1354
rigid molecule structural analysis, 1351–1352, 1351*F*
- magic angle spinning (MAS) NMR
basic concepts, 1828
biological applications, 927–929
food and nutritional science applications, 677
inorganic structural analysis, 2713*F*
instrumentation, 1878
metabonomic studies, 2061
synthetic polymer analysis, 2226–2227, 2226*F*
tissue extract analyses, **925–930**
- membrane studies, 1504, 1505 *T*, 1506*F*
metabonomic studies, 2058–2059, 2060*F*, 2061*F*, 2062*F*, 2644
NMR spectrometers, 1878–1879
nuclear spin properties, 905–906, 906 *T*
organic molecule structural analyses
general discussion, 2718–2720
proton chemical shift, 2718–2720, 2719*F*, 2720*F*
stereochemical assignments, 2721–2723, 2722*F*
through-bond spin–spin coupling analysis, 2720–2721
pharmaceutical research and development, 2745–2746, 2746*F*
plant science applications, 2184–2186, 2184 *T*, 2185*F*, 2187
process analytical technology (PAT), 2655 *T*, 2656
protein and peptide analyses
historical background, 2272
orientation studies, 1508–1509
protein denaturation studies, 862*F*, 863–864
protein–ligand interactions, 1397–1398
quantitative NMR (qNMR), 2331–2332, 2333 *T*
stray field imaging (STRAFI), 1649–1650, 1650*F*, 1651*F*, 1651 *T*, 1652*F*
synthetic polymer analysis, 2226–2227
dynamic and exchange NMR, 2231–2234, 2232*F*, 2233*F*
high-resolution magic-angle spinning (MAS) investigations, 2226*F*
low-resolution analyses, 2227–2228, 2227*F*
spin diffusion NMR, 2234–2235, 2235*F*
- tissue extract analyses, **925–930**
basic concepts, 925
cellular environment analyses, 927
future research areas, 929–930
general discussion, 925
liver sample spectra, 926*F*, 929*F*
magic angle spinning (MAS) NMR, 925, 926*F*
metabonomic studies, 2058–2059
pulse sequence observing strategies, 927, 928*F*
sample preparation, 925–926
in vivo hydrogen-1 magnetic resonance spectroscopy (¹H NMR), **1107–1111**
hydrogen-2 magnetic resonance spectroscopy (²H NMR)
cell research, 220
characteristics, 213 *T*, 429 *T*
chemically induced dynamic nuclear polarization (CIDNP), 318 *T*
drug metabolism analyses, 431
exchange experiments, 2593*F*, 2594
food and nutritional science applications, 663 *T*, 664–665
in vivo applications, 1100 *T*, 1105
labelled material studies, 1249, 2273
liquid crystals
liquid crystalline solutions, 1352
molecular dynamics research, 1354–1355
orientational order parameters, 1353–1354, 1354*F*
phase structure determinations, 1354, 1355*F*
membrane studies
advantages/disadvantages, 1505 *T*
general discussion, 1504
lipid orientational information, 1507–1508
motion-order amplitude parameters, 1509*F*, 1510*F*
properties, 1505 *T*
spectral data, 1506*F*
plant science applications, 2184 *T*, 2187
protein and peptide analyses, 2273
spin-1/2 NMR spectra, 2582 *T*
synthetic polymer analysis, 2235–2236
hydrogen bromide (HBr), 775 *T*
hydrogen fluoride (HF), 1480–1481
hydrogen iodide (HI), 1479–1480

- hydrogen (H) (*continued*)
 interstellar abundances, 1075*F*
 interstellar and circumstellar molecules, 1070*T*
 isotopes
 delta (δ) values, 1229*T*
 isotope abundance ratios, 1229*T*
 isotope abundance variations
 characteristics, 1229–1230
 international reference water sample data, 1229*F*, 1230
 sample preparation, 1230
 radionuclide sources, 2992*T*
 magnetic moment, 520*T*
 metal–carbon–hydrogen complexes, 1691–1692, 1691*F*
 nuclei characteristics, 1099*T*, 1976*T*
 photoionization mass spectrum, 1460–1461, 1462*F*
 protein and peptide analyses, 2098
 scattering cross-sections, 1024*T*
 tritium magnetic resonance spectroscopy (^3H NMR), 2857–2860
 advantages, 2857
 applications
 chiral methyl group analysis, 2858–2859
 macromolecular analysis, 2859–2860
 new tritium labelling reagents, 2858
 selective tritiation procedures, 2858
 substrate–receptor interactions, 2859
 nuclei characteristics, 2857
 sample preparation, 2857–2858
 van der Waals radii, 2554*T*
 hydroxyamides, 1791*F*
 hydroxybenzaldehyde, 1486*T*
 hydroxybenzaloxime, 1486*T*
 hydroxybenzoic acid, 1486*T*
 hydroxybutyric acid, 1486*T*
 hydroxyhippuric acid, 1486*T*
 hydroxyindoleacetic acid, 1486*T*
 hydroxyisobutyric acid, 1486*T*
 hydroxyisocaproic acid, 1486*T*
 hydroxyisovaleric acid, 1486*T*
 hydroxylamines, 1791*F*
 hydroxylammonium, 1791*F*
 hydroxymethylvaleric acid, 1486*T*
 hydroxyoctanoic acid, 1486*T*
 hydroxyphenylacetic acid, 1486*T*
 hydroxyphenyl–hydroxypropionic acid, 1486*T*
 hydroxyphenyllactic acid, 1486*T*
 hydroxyphenylpyruvic acid, 1488, 1488*F*, 1489*F*
 hydroxyphenyl–pyruvic oxime, 1486*T*
 hydroxysebacic acid, 1486*T*
 hydroxytetraacain hydrochloride, 2243, 2243*F*
 hyperacute stroke, 1617, 1618*F*, 1619*F*
 hyperfine interactions
 electronic spin resonance (EPR)
 spectroscopy, 519, 519*F*, 520*F*, 520*T*, 521*F*
 Mössbauer spectroscopy, 1587–1590, 1588*F*, 1590*F*
 hyperpolarization, 963–964, 1658–1659
 hyperpolarized noble gases
 magnetic resonance imaging (MRI), 971–978
 background information, 971
 imaging methods
 diffusivity maps, 975–976, 976*F*
 dynamic imaging, 977, 977*F*
 intrapulmonary partial oxygen pressure (pO_2), 976–977
 ventilation images, 974–975, 975*F*
 xenon-129 (^{129}Xe) exchange methods, 977–978, 977*F*
 implementation techniques
 B_0 field strength, 973
 pulse sequence factors, 973–974, 974*F*
 radio-frequency hardware, 973
 polarization mechanisms, 971–973, 972*F*
 spin-exchange optical pumping (SEOP) technique, 971–973, 972*F*, 1659
 hyper-Raman effect
 applications, 1917, 1917*F*, 1918*F*, 1919*F*
 basic concepts, 1913–1914, 1914*F*
 hypervalent radicals, 1764*T*
 hyphenated nuclear magnetic resonance (NMR), 979–983
 applications, 982
 capillary electrophoresis (CE), 1879–1880
 extended techniques, 980–981, 981*F*
 food and nutritional science applications, 665
 general discussion, 979
 high-performance liquid chromatography (HPLC), 431–432, 979–980, 1879–1880, 2186, 2186*F*
 high-performance liquid chromatography (HPLC)–solid-phase extraction (SPE)–nuclear magnetic resonance (NMR) technique, 980, 981*F*
 mass spectrometry (MS), 2186, 2186*F*
 metabonomic studies, 2062
 multiple chromatographic techniques, 982
 pharmaceutical research and development, 2640, 2643*F*
 sensitivity factors, 981–982, 982*F*
 signal-to-noise ratio (SNR), 982*F*

 - sample preparation
 - fusions and sinters, 994
 - general discussion, 993–994

- inductively coupled plasma–mass spectrometry (ICP–MS) (*continued*)
 hydrofluoric acid (HF)-containing mixtures, 994
 partial digestion, 994
 sector field–inductively coupled plasma–mass spectrometry (SF–ICP–MS), 992
 spectroscopic interferences
 collision–dynamic reaction cells (DRCs), 993
 polyatomic radicals, 992–993
 vapor generation, 995–996
 inelastic electron tunnelling spectroscopy, 2467–2468, 2467*F*, 2468*F*, 2469*F*, 2821
 inelastic neutron scattering (INS)
 spectroscopy
 applications, 1024–1034
ab initio techniques, 1032–1033, 1033*F*
 background information, 1024
 coherent INS spectroscopy, 1029–1031, 1030*F*, 1031*F*, 1032*F*
 incoherent INS spectroscopy, 1031–1033, 1032*F*, 1033*F*
 neutron Compton scattering (NCS), 1033–1034, 1034*F*
 quasielastic scattering, 1025–1027, 1026*F*, 1027*F*
 tunnelling spectroscopy, 1027–1028, 1028*F*, 1029*F*
 basic concepts
 energy ranges and timescales, 1036*F*
 neutron characteristics, 1036*T*
 neutron sources, 1035–1037
 real space and reciprocal space diagrams, 1037*F*
 coherent scattering, 1024–1025, 1024*T*
 incoherent scattering, 1024–1025, 1024*T*
 instrumentation, 1035–1044
 electron volt (eV) spectrometer, 1043–1044, 1043*F*
 energy range (0–1000 meV)
 filter spectrometer, 1042–1043
 MARI direct-geometry spectrometer, 1042, 1043*F*
 neutron characteristics, 1041–1042
 TOSCA indirect-geometry spectrometer, 1042, 1042*F*
 triple-axis spectrometer, 1041–1042, 1041*F*
 energy range (> 1000 meV), 1043–1044
 energy range (10 meV)
 backscattering crystal analyser, 1038–1040, 1039*F*
 IRIS spectrometer, 1038–1040, 1039*F*
 neutron spin echo spectrometer, 1040–1041, 1040*F*
 quasielastic scattering, 1037–1038
 time-of-flight (TOF) INS spectroscopy, 1037–1038, 1038*F*
 energy transfer coverage, 1037*F*
 future development areas, 1044
 surface studies, 2821
 inelastic scattering, 2406–2408
 infrared (IR) spectroscopy, 1174–1186
 applications
 donor molecule spectral changes, 1176–1177, 1177*F*
 metal–ligand/metal–isotope analyses, 1178–1179
 resonance interactions, 1176–1177, 1177*F*
 selection rules, 1176, 1176*F*, 1176*T*
 symmetry changes, 1177–1178, 1178*F*
 artwork analyses, 23–38
 background information, 23
 biomaterials
 general discussion, 24–26
 ivory objects, 25*F*, 26*F*
 Roman die, 25*F*
 scrimshaw specimens, 25, 27*F*
 comparison studies, 23–24
 faience, 24
 glasses, 24
 medieval manuscripts, 28*T*, 31–33, 32*T*, 33*F*, 34*F*, 35*F*, 36*F*

 black inorganic pigments, 28*T*
 blue inorganic pigments, 28*T*
 brown/orange inorganic pigments, 28*T*
 general discussion, 26–31
 green inorganic pigments, 28*T*
 organic pigments and dyes, 30*T*
 red inorganic pigments, 29*T*, 31*F*, 736*F*
 white inorganic pigments, 29*T*, 32*F*
 yellow inorganic pigments, 29*T*
 plastics, 24
 wall paintings, 34–37, 36*F*, 37*F*, 735–736, 736*F*
 band assignments, 1175–1176
 basic concepts, 1218–1223
 absorption mechanisms
 dipole moment, 1219
 electromagnetic radiation, 1218–1219
 general discussion, 1218–1220
 photon energy, 1218
 dipole autocorrelation function, 1220*F*
 fluid interactions, 1220–1221, 1220*F*
 general discussion, 1174
 quantum theoretical calculations, 1221–1222
 relative energy calculations, 1221*F*
 vibrational spectra calculations, 1221, 1221*F*
 vibration rotation spectra, 1222, 1222*F*
 biological applications, 142–152
 aqueous solutions limitations, 142–144, 142*F*, 143*F*, 143*T*
 biological macromolecules, 144, 144*F*
 botanical studies, 146–148, 147*F*, 148*F*, 149*F*
 characteristic spectral bands, 145*T*
 clinical studies, 148–151
 food and nutritional science applications, 148–151, 150*F*
 internal reflection materials, 143*T*
 isotopic labelling, 151*F*
 microbiological studies, 144–146, 145*T*
 protein and peptide analyses, 148–151, 150*F*, 151*F*
 search parameters, 145*T*
 zoological studies, 148–151
 calibration regulatory standards, 197*T*
 chromatography–infrared (IR) spectroscopy
 analyses, 298–303, 304–308
 background information, 298
 chromatogram generation, 304–305
 gas chromatography–Fourier transform infrared (GC–FTIR) spectroscopy
 biomedical applications, 299
 chromatogram generation, 304–305
 environmental pollutants, 299
 essential oils analyses, 299
 flowcell (light pipe) approach, 298
 food analyses, 300
 general discussion, 305
 industrial applications, 298
 interface characteristics, 308
 interface diagrams, 305*F*
 light pipe GC–IR, 305, 305*F*
 matrix isolation GC–IR, 305–306, 305*F*
 matrix-isolation (MI) approach, 300–301, 300*F*
 petrochemical applications, 298
 polymer analyses, 300
 subambient solute trapping (direct-deposition) approach, 300
 subambient solute trapping GC–IR, 305, 305*F*
 general discussion, 302–303, 304
 high-performance liquid chromatography–Fourier transform infrared (HPLC–FTIR) spectroscopy
 flowcell approach, 301
 solvent-elimination approach, 301
 interface characteristics, 308
 liquid chromatography–Fourier transform infrared (LC–FTIR) spectroscopy
 flow cell LC–IR, 306, 306*F*
 general discussion, 306
 interface characteristics, 308
 interface diagrams, 306*F*
 microbore LC–IR, 307
 mobile phase elimination LC–IR, 306–307, 306*F*
 supercritical fluid chromatography–Fourier transform infrared (SFC–FTIR) spectroscopy, 301–302, 307
 thin-layer chromatography–Fourier transform infrared (TLC–FTIR) spectroscopy, 302
 diffuse reflectance TLC–IR, 307–308, 307*F*
 general discussion, 307–308
 photoacoustic TLC–IR, 308
 solute transfer TLC–IR, 308
 coordination compounds
 ammine complexes, 1181, 1183*F*
 aquo/hydroxo complexes, 1184
 carbonyl complexes, 1184–1185
 β -diketones, 1184, 1184*F*
 dioxygen (O₂) complexes, 1185
 halogeno complexes, 1185
 lattice water, 1183–1184

isobutyl methyl ketone, 1195*F*
para-nitroaniline, 1196*F*
vibrational frequency, 1188, 1189*F*
vibrational interactions, 1188–1189, 1189*F*, 1190*T*
- organometallic compounds
metal alkanes, 1186
metal alkenes, 1186, 1186*F*
metal alkynes, 1186
- pharmaceutical research and development, 2640, 2643*F*
- polymer analyses, 2213–2220
chemical property determinations
polymerization reactions, 2217, 2218*F*
spatial resolution, 2218, 2219*F*
time-dependent phenomena, 2217–2218, 2219*F*
general discussion, 2213
spectroscopic considerations, 2213–2214
structure determinations
chain interactions, 2216
general discussion, 2214
polymer chain identification, 2214, 2215*F*
processing-induced orientation, 2216–2217
rotational isomers, 2215–2216, 2216*F*
- process analytical technology (PAT), 2655*T*
- reflection–absorption infrared spectroscopy (RAIRS), 2814, 2814*F*, 2815*F*
- sample handling methods, 1174–1175
- sample preparation methods, 1210–1217
background information, 1210
emission spectroscopy, 1217
external reflection methods
characteristics, 1214–1216
diffuse reflection, 1215*F*, 1216*F*
reflection and reflection-absorption surfaces, 1215*F*
surface-based reflection and reflection-absorption, 1215*F*
- internal reflection methods
characteristics, 1213–1214
evanescent wave, 1213*F*
horizontal ATR (HATR) units, 1214*F*
single-reflection ATR accessory, 1214*F*
total internal reflection plot, 1213*F*
- liquid chromatography (LC) techniques, 1217
- microsampling methods, 1216–1217
- photoacoustic spectroscopy (PAS), 1216, 1216*F*
- pyrolysis, 1217
- separation techniques, 1217
- transmission measurements
Christiansen effect, 1212*F*
gases, 1213
liquids, 1210–1211, 1211*F*
solids, 1211–1213, 1212*F*
window materials, 1211*T*
- spectrometers, 1199–1209
background information, 1199
dispersive double-beam spectrometers, 1199, 1200*F*
Fourier transform spectrometers
basic optics, 1200*F*
commercial instrumentation, 1208–1209
cosine waves, 1200*F*
detectors, 1206–1207, 1207*F*, 1207*T*
frequency range and resolution, 1201–1203, 1202*F*
general discussion, 1199–1200
interferograms, 1201*F*, 1202–1203, 1203*F*, 1204*F*, 1205*F*
optical arrangement, 1201*F*
scanning mechanisms, 1205–1206, 1205*F*, 1206*F*
single-beam spectra, 1201*F*
step-scan instruments, 1207–1208, 1208*F*
infrared (IR) region, 1199, 1199*F*
interferograms
measurement techniques, 1202–1203, 1203*F*, 1204*F*
signal processing, 1203–1205, 1205*F*
two-dimensional (2D) infrared spectroscopy, 104
infrared (IR) wavelengths, 451*F*, 454–455
infrared lasers, 893, 1301
Infrared Space Observatory, 1067, 1069*F*
infrared sum frequency generation (IRSFG), 1928*F*, 1928*T*, 1929
in-line process monitoring, 2653*F*
- inorganic compounds/minerals
fluorescence microscopy, 623
Fourier transform Raman spectroscopy, 739–740
infrared (IR) and Raman spectroscopy
general discussion, 1179–1181
vibrational frequencies
diatomic molecules, 1179*T*
fundamental vibrations, 1183*T*
octahedral molecules, 1182*F*, 1182*T*
square-planar molecules, 1181*F*, 1182*T*
tetrahedral molecules, 1180*F*, 1181*T*
tetraatomic molecules, 1180*F*, 1180*T*
triatomic molecules, 1179*F*, 1179*T*
- Mössbauer spectroscopy, 1578–1579, 1580*F*
- nuclear magnetic resonance (NMR) spectroscopy, 2708–2717

- liquid extraction surface sampling probe/ionization
 characteristics, 1545–1546*T*, 1553–1554
 liquid microjunction surface sampling probe (LMJ–SSP), 1545–1546*T*, 1554, 1554*F*
 sealing surface sampling probe, 1553–1554, 1553*F*
- liquid secondary-ion mass spectrometry (LSIMS), 566
- litharge, 29*T*
- lithium (Li)
 atomic spectroscopic analyses, 2129–2131*T*
 cosmic abundances, 414*F*
 dilithium fluoride (Li_2F), 1758–1759, 1759*F*
 interstellar abundances, 1075*F*
in vivo applications, 1100*T*, 1104
 lithium-7 magnetic resonance spectroscopy (^7Li NMR)
 cellular systems, 1884–1885, 1885*F*
 characteristics, 429*T*
 chemical shift studies, 2586*T*
 drug metabolism analyses, 430, 438–439
 in vivo applications, 1100*T*, 1104
 nuclei characteristics, 2585*T*
 perfused organ research, 2099*T*, 2105
 stray field imaging (STRAFI), 1651*T*
 lithium calcium aluminum hexafluoride (LiCaAlF_6), 1063–1064, 1064*F*
 lithium iodate (LiIO_3), 1909–1910*T*
 lithium niobate (LiNbO_3), 1909–1910*T*
 lithium strontium aluminum hexafluoride (LiSrAlF_6), 1063–1064, 1064*F*
 lithium superoxides (Li^+O_2^-), 1479–1480, 1480*F*, 1480*T*
- NMR active nuclei, **1881–1889**
 biological applications
 cellular systems, 1884–1885, 1885*F*
 contrast reagents, 1882–1884, 1883*T*, 1884*F*
 mediated membrane transport, 1886–1887
 chemical applications
 alkalide ions, 1888
 covalently bound lithium, 1887
 metal ion complexation studies, 1887–1888, 1888*F*
 electric field gradient (EFG), 1881–1882
 energy level splittings, 1883*F*
 nuclei characteristics, 1099*T*, 1881, 1882*T*, 2585*T*
 quadrupolar interactions, 1881–1882, 1883*F*
 nuclei characteristics, 1976*T*
 pharmaceutical compounds, 2135*T*
 sample dilution factors, 176*T*
 spectral interferences, 175*T*
- lithopone, 29*T*
- Littrow spectrometer, 47–48, 48*F*
- liver research
 carbohydrate metabolism, 1100–1101, 1101*F*
 lipid research, 1102–1103
 magnetic resonance imaging (MRI), 1598, 1600*F*, 1611–1613
 nuclear magnetic resonance (NMR) spectroscopy
 fluorine-19 magnetic resonance spectroscopy (^{19}F NMR), 1103–1104, 1103*F*
 magic angle spinning (MAS) NMR, 926*F*, 927–929, 929*F*
 nitrogen-15 nuclear magnetic spectroscopy (^{15}N NMR), 2105
 phosphorus-31 magnetic resonance spectroscopy (^{31}P NMR)
 disease research, 1116
 general discussion, 1116
 liver metabolism, 1116
 perfused organ research, 2105
 spectral interpretations, 1116
- lobsters, 657–659*T*
- locally weighted regression (LWR), 389, 389*F*, 390*F*
- local origin (LORG), 2070, 2071*T*, 2073*T*
- longitudinal-field muon spin rotation (LF– μSR), 1712*F*, 1713
- long-range surface plasmon resonance (LRSPR), 2807, 2810*F*
- low-area flat surfaces, 2813–2815, 2814*F*, 2815*F*
- low energy electron Mössbauer spectroscopy (LEEMS), 1568
- low-field NMR, **1357–1371**
 background information, 1357
 Earth's field NMR
 basic concepts, 1364–1368
 dynamic nuclear polarization (DNP), 1367*F*
 free induction decay (FID) plot, 1363*F*
 heteronuclear coupling, 1366*F*
 instrumentation, 1364*F*, 1365*F*
 spectral comparison studies, 1364*F*
 three-dimensional (3D) imaging, 1366*F*, 1368
 time domain measurements, 1365*F*
 enhancement modification strategies, 1362, 1362*F*
 field homogeneity, 1358–1359
 general discussion, 1371
 low frequency ringdown times, 1368–1369
 magnetic field strengths, 1357–1358
 non-Faraday detection, 1358
 permanent magnet systems, 1359, 1359*F*
 polarization transfer methods, 1367*F*, 1368
 portable systems, 1363, 1363*F*
 signal amplitude, 1357–1358
 sub-megahertz NMR, 1364–1368
 superconducting quantum interference device (SQUID) detectors, 1358, 1368*F*, 1369–1370, 1369*F*
- time domain measurements
 ACT Profile Mouse and Lift, 1362*F*
 characteristics, 1359–1362
 decay curves, 1360*F*
 Earth's field NMR, 1365*F*
 enhancement modification strategies, 1362, 1362*F*
 liquid crystal diffusion–diffusion correlation measurements, 1361*F*
 NMR mole (MOBILE Lateral Explorer), 1361*F*
 NMR Mouse, 1361*F*, 1362*F*, 1363*F*
 relaxation spectra, 1360*F*
 zero-field NMR, 1370–1371, 1370*F*
- low-resolution NMR spectroscopy, 678, 678*T*
- Lowry/Folin–Ciocalteu method, 170
- Lucka Bible, 31–33, 32*T*, 33*F*
- luminescence spectroscopy
 basic concepts, **1372–1391**
 chemiluminescence, 1390–1391
 emission/excitation spectra, 1375–1376, 1376*F*
 energy transfer processes
 characteristics, 1384
 donor–acceptor processes, 1384–1385, 1385*F*

- experimental example, 1385–1386, 1386*F*, 1387*F*
 non-radiative mechanisms, 1384–1385, 1385*F*
 phonon-assisted energy transfer, 1385, 1385*F*
 radiative mechanisms, 1384
 excimers/exciplexes
 characteristics, 1386–1387
 inorganic exciplexes, 1388–1390, 1388*F*, 1389*F*, 1389*T*, 1390*F*
 organic exciplexes, 1387–1388, 1387*F*
 excited-state distortions, 1373–1375, 1375*F*
 Franck–Condon behavior, 1373–1375, 1374*F*
 general discussion, 1372
 luminescence lifetimes
 fluorescence versus phosphorescence, 1377
 luminescence quantum yields, 1377–1378
 theoretical considerations, 1376–1377, 1377*F*
 luminescence quantum yields
 environmental factors, 1378–1379
 general discussion, 1377–1378
 structural rigidity, 1378, 1378*F*
 substitution factors, 1378
 transition type, 1378
 molecular photoluminescence
 fluorescence, 628, 629, 1373
 Jablonski energy level diagram, 628–629, 628*F*, 629*F*, 1372, 1372*F*
 non-radiative relaxation processes, 1373
 phosphorescence, 628, 1372*F*, 1373
 spin-allowed/spin-forbidden transitions, 1373
 non-radiative relaxation processes
 internal conversion, 1373
 intersystem crossing, 629, 1372*F*, 1373
 non-radiative de-excitation, 1373
 vibrational relaxation, 1373
 photoluminescence case studies
 inorganic luminophores, 1380–1381, 1381*F*
 organic luminophores, 1379–1380, 1379*F*, 1380*F*
 quenching processes
 characteristics, 1382
 dynamic (collisional) quenching, 1382–1383, 1382*F*
 experimental example, 1383–1384
 quenching constants, 1384*T*
 static quenching, 1382
 Stern–Volmer calculation, 1382–1383, 1382*F*, 1383*F*, 1384*F*
 fluorescence theory, 628–634
 emission characteristics
 lifetime, 629–630, 630*F*
 quantum yield (ϕ), 629–630
 solvent reorientation, 629
 Stokes shift, 629
 fluorescence, 628, 629
 fluorescence anisotropy, 632–634, 633*F*
 fluorescence quenching
 characteristics, 630–631
 collisional quenching, 630–631
 quenching mechanisms, 631
 static quenching, 631
 Stern–Volmer plot, 631
 intersystem crossing, 629
 Jablonski energy level diagram, 628–629, 628*F*, 629*F*
 phosphorescence, 628
 resonance energy transfer (RET), 631–632, 632*F*, 633*F*
 inorganic compounds, 503–504
 optically active inorganic condensed matter, 1057–1066
 analytical techniques
 absorption measurements, 1060–1063, 1061*F*
 high-resolution laser techniques, 1062, 1063*F*, 1065*F*
 selective excitation, 1061, 1062*F*
 zero-order excitation spectroscopy, 1061
 crystal field
 colour centres, 1058
 host characteristics, 1058–1060, 1060*F*
 impurity interactions, 1057
 lanthanide ion doping, 1057, 1058*F*
 spectroscopic characteristics, 1057
 transition metal ion doping, 1057–1058, 1059*F*
 electron–phonon coupling, 1063–1064, 1064*F*, 1065*F*
 impurity interactions, 1057
 luminescence phenomena studies, 1063–1064, 1064*F*, 1065*F*
 technological applications, 1065–1066
 organic compounds, 504
 lunar material investigations, 419, 419*F*, 420
 lutetium (Lu)
 lutetium-175 magnetic resonance (^{175}Lu NMR) spectroscopy, 814–815
 lutetium oxyorthosilicate (LSO), 2247
 nuclei characteristics, 1976*T*
 lysergic acid diethylamide (LSD), 694
 lysine, 131–135*T*
 lysozyme spectra, 2372*F*

 nuclei characteristics, 786*T*
 organoaluminum(III) compounds, 791–793, 792*T*
 plant science applications, 2184*T*, 2187
 solid-state aluminum-27 (^{27}Al) magic angle spinning NMR, 795
 sonically-induced narrowing NMR (SINNMR) technique, 2616
 background information, 404, 1086, 1646, 1654
- basic concepts, 1638–1645
 back-projection imaging, 1640, 1641*F*
 chemical shifts, 1086–1087, 1086*F*
 contrast-to-noise ratio (CNR), 1644
 general discussion, 1638–1639, 1645
 phase encoding, 1641–1642, 1642*F*
 relaxation behavior, 1087, 1088*T*
 sensitivity factors, 1087, 1088*T*
 signal-to-noise ratio (SNR), 1643–1644
 slice selection, 1642–1643, 1642*F*
 spatial localization, 1108–1109, 1639
 spatial resolution, 1639–1642
 spectral resolution, 1086–1087
 spectral spatial selectivity, 1645
 spin warp imaging, 1640, 1642*F*
- biological applications, 1593–1603
 applications
 cardiovascular system, 1596–1598, 1598*F*, 1599*F*
 central nervous system, 1594–1596, 1596*F*, 1597*F*
 kidney research, 1600–1601, 1601*F*
 liver research, 1598, 1600*F*
 musculoskeletal system, 1601, 1601*F*
 oncological studies, 1602, 1602*F*
 characteristics, 1593
 clinical flow studies, 1615–1621
 arterial research, 1620
 brain research, 1617
 flow measurement methods, 1615
 general discussion, 1621
 kidney research, 1621
 thorax research, 1619
 tissue perfusion, 1616–1617
 tumor research, 1621
 diffusion-weighted water suppression, 1593–1594
 future research areas, 1602
 operation conditions, 1594, 1595*F*
 rodent brain slices, 1597*F*
- boron-11 magnetic resonance spectroscopy (^{11}B NMR)
 characteristics, 429*T*
 chemical shifts, 787–790, 788*T*
 drug metabolism analyses, 430–431
in vivo applications, 1100*T*, 1105
 nuclei characteristics, 786*T*
 organylborane compounds, 788–790, 788*T*
 plant science applications, 2184*T*, 2187
 polyhedral boranes, 790
 stray field imaging (STRAFI), 1651*T*
- bromine-79/81 magnetic resonance (^{81}Br NMR) spectroscopy, 771–778
 conducting and semiconducting lattices, 777
 electric field gradient (EFG), 771–773
 general discussion, 771
 halide-cation interactions, 776–777
 halide-ligand interactions, 776
 nuclear properties, 771*T*
 quadrupolar interactions, 771–773, 772*F*
 residual dipolar coupling, 775
 shielding, 775–776
 spin-1/2 NMR spectra, 2582*T*
 spin-spin couplings, 774–775, 775*T*
- cadmium-113 magnetic resonance spectroscopy (^{113}Cd NMR), 2184*T*, 2187
- carbon-13 magnetic resonance spectroscopy (^{13}C NMR)
 analytical methods, 355–364
 attached-proton test (APT), 358–360, 358*F*, 359*F*
 chemical shift experiments, 361–363, 361*F*, 362*T*, 363*T*
 distortionless enhancement by polarization transfer (DEPT) test, 359, 359*F*, 360*F*
 general discussion, 355
 heteronuclear decoupling, 356–357, 357*F*
 insensitive nuclei enhanced by polarization transfer (INEPT) test, 360
 multiple pulse experiments, 358–360
 nuclear Overhauser effect (NOE), 357–358, 358*T*
 single-pulse Fourier transform NMR, 355–356, 356*F*
 spectral assignment tests, 361–363
 structural determinations, 361–363
 two-dimensional nuclear magnetic resonance (2D NMR)
 spectroscopy, 360–361, 360*T*, 361*F*
 biomedical applications, 1109–1110, 1110*F*, 1111, 2099*T*, 2103–2104
- carbohydrate analyses
 carbon-proton/carbon-carbon spin couplings, 209
 multidimensional heteronuclear analysis, 209, 210*F*
 primary analysis and assignment, 209
- carbohydrate metabolism
 brain research, 1101–1102
 cardiac studies, 1101
in vivo applications, 1100–1101
 liver research, 1100–1101, 1101*F*
 muscle research, 1101
- carbon-13 cross polarization-magic angle spinning nuclear magnetic resonance (^{13}C CP-MAS NMR) spectroscopy
 biopolymers, 899–901
 blend polymers, 898–899
 coals/coal products, 904
 fibrous proteins, 901–902
 fluoropolymers, 898
 food analyses, 904

 poly(vinyl alcohol) (PVA), 897–898, 897*F*
 synthetic polymers, 894–897
 synthetic polypeptides, 899–901, 900*F*, 901*F*, 902*F*
in vivo applications
 biomedical research, 1100*T*
 carbohydrate metabolism, 1100–1101
 cell research, 216–219, 217*F*, 218*F*
 drug metabolism analyses, 436, 438*F*
 lipids, 1102
 whole-body research, 1099–1101
labelled material studies, 1247–1249, 1248*F*, 1249–1252, 1250*F*, 2273
lipids
 adipose tissue, 1102
 brain research, 1103
 food and nutritional science applications, 678*T*
 in vivo applications, 1102
 liver research, 1102–1103
magic angle spinning (MAS) NMR instrumentation, 1878
liquid crystal analyses, 1437–1438
synthetic polymer analysis, 2226–2227, 2226*F*, 2228–2230, 2229*F*, 2230*F*
 tissue extract analyses, 929
membrane studies, 1504, 1505*T*, 1506*F*, 1507–1508
nuclei characteristics, 355, 355*T*, 1099*T*
organic molecule structural analyses, 2723–2727, 2723*F*, 2724*F*, 2727*F*
plant science applications, 2184–2186, 2184*T*, 2187
protein and peptide analyses, 2273
protein–ligand interactions, 1394
quantitative NMR (qNMR), 2331–2332
relaxation reagents, 257*F*
self-decoupling, 2583*F*
spectral editing pulse sequences, 1846–1847, 1847*F*, 1848*F*, 1848*T*
spin-1/2 NMR spectra, 2581–2582, 2581*F*, 2582*F*, 2582*T*
synthetic polymers
 chemical identification, 2223–2224
 cross polarization (CP) analyses, 2228–2230
 dipolar decoupling (DD) analyses, 2228–2230
 dynamic and exchange NMR, 2231–2234, 2234*F*
 high-resolution magic-angle spinning (MAS) investigations, 2226–2227, 2226*F*, 2228–2230, 2229*F*, 2230*F*
 molecular weight determination, 2223–2224
 multidimensional NMR, 2230–2231, 2231*F*
 one-dimensional (1D) MAS method, 2233–2234, 2234*F*
 oriented polymers, 2235–2236
 relaxation studies, 2224–2226, 2225*F*
 separated local field (SLF) analyses, 2230–2231
 sequence analysis, 2224, 2224*F*
 solution-state studies, 2223–2224
 wideline separation (WISE) analyses, 2230–2231, 2231*F*
cell research, 212–220
 background information, 212–213
carbon-13 magnetic resonance spectroscopy (^{13}C NMR), 213*T*, 216–219, 217*F*, 218*F*
fluorine-19 magnetic resonance spectroscopy (^{19}F NMR), 213*T*, 220
hydrogen-1 magnetic resonance spectroscopy (^1H NMR), 213*T*, 219–220, 219*F*, 220*F*
hydrogen-2 magnetic resonance spectroscopy (^2H NMR), 213*T*, 220
large-scale/high-density cell culture procedures, 213–215, 214*F*
nitrogen-14 nuclear magnetic spectroscopy (^{14}N NMR), 213*T*
nitrogen-15 nuclear magnetic spectroscopy (^{15}N NMR), 213*T*
oxygen-17 magnetic resonance spectroscopy (^{17}O NMR), 213*T*, 220
phosphorus-31 magnetic resonance spectroscopy (^{31}P NMR), 213*T*, 215–216, 215*F*
potassium-39 magnetic resonance spectroscopy (^{39}K NMR), 213*T*
sodium-23 magnetic resonance spectroscopy (^{23}Na NMR), 213*T*, 220
cesium-133 magnetic resonance spectroscopy (^{133}Cs NMR), 678*T*, 2184*T*, 2187
chlorine-35/37 magnetic resonance spectroscopy ($^{35}\text{Cl}/^{37}\text{Cl}$ NMR), 771–778
biological chloride analyses, 773–774, 774*F*
conducting and semiconducting lattices, 777
electric field gradient (EFG), 771–773
general discussion, 771
halide–cation interactions, 776–777
halide–ligand interactions, 776, 777*F*
nuclear properties, 771*T*
plant science applications, 2184*T*, 2187
quadrupolar interactions, 771–773, 772*F*
residual dipolar coupling, 775
shielding, 775–776
spin-1/2 NMR spectra, 2582*T*
spin–spin couplings, 774–775, 775*T*
two-dimensional multiple-quantum (2D2Q) nuclear magnetic resonance spectroscopy, 777
clinical applications, 1604–1614
 anatomical imaging, 1605–1608, 1606*F*, 1607*F*, 1608*F*, 1609*F*
 blood serum and plasma, 1608–1611, 1612*F*
 brain research, 1610*F*
 contrast agents, 1608, 1608*F*
 dynamic contrast-enhanced magnetic resonance imaging, 1610–1611, 1617
 functional magnetic resonance imaging (fMRI), 1611, 1613*F*
 historical background, 1604
 interventional techniques, 1611–1613
 kidney research, 1610*F*
 magnetic field strengths, 1604
 magnetic resonance angiography (MRA), 1609, 1610*F*, 1616, 1616*F*

- magnetic resonance imaging (MRI) (*continued*)
 magnetic resonance spectroscopy (NMR), 1613
 (partial) saturation recovery sequence, 404–406, 405*F*, 405*T*
 phase contrast (PC) method, 1608–1611, 1609*F*, 1615–1616
 physiological research, 1608–1611
 time-of-flight (TOF) method, 1609, 1610*F*, 1615
 tissue extract analyses, 404–406, 405*F*, 405*T*
 tissue motion studies, 1611, 1613*F*
 tissue perfusion, 1610–1611, 1617
 clinical flow studies, **1615–1621**
 arterial research
 aorta, 1610*F*, 1620
 pulmonary arteries, 1620–1621
 renal arteries, 1610*F*
 brain research
 aneurysms, 1610*F*
 cerebrospinal fluid (CSF) flow, 1619, 1619*F*
 dynamic contrast-enhanced magnetic resonance imaging, 1610–1611, 1612*F*
 flow-restrictive lesions, 1617
 hyperacute stroke, 1617, 1618*F*, 1619*F*
 subclavian steal, 1618–1619
 vascular flow reserve, 1617–1618
 general discussion, 1615, 1621
 kidney research, 1610*F*, 1621
 magnetic resonance angiography (MRA), 1609, 1610*F*, 1616, 1616*F*
 phase contrast (PC) method, 1608–1611, 1609*F*, 1615–1616
 thorax research
 myocardial perfusion, 1619–1620, 1620*F*
 valvular heart disease, 1619
 time-of-flight (TOF) method, 1609, 1610*F*, 1615
 tissue motion studies, 1611, 1613*F*
 tissue perfusion
 arterial spin labelling, 1617
 dynamic contrast-enhanced magnetic resonance imaging, 1610–1611, 1617
 general discussion, 1616–1617
 tumor research, 1621
 contrast mechanisms, **404–413**
 anatomical imaging, 1608, 1608*F*
 artifact analysis, 409–410, 410*F*
 chiral (LSR) shift reagents, 259–261, 260*F*
 diffusion effects, 411–412
 flow effects, 411, 411*F*
 general discussion, 412
 magnetization transfer contrast (MTC), 412, 412*F*
 standard sequences
 general discussion, 404–406
 inversion recovery sequence, 406–409, 408*F*
 (partial) saturation recovery sequence, 404–406, 405*F*, 405*T*
 spin-echo sequence, 406, 407*F*
 susceptibility effects, 410–411
 copper-63/65 nuclear magnetic resonance ($^{63/65}\text{Cu}$ NMR) spectroscopy, 2582*T*
 diagnostic aspects, 2248–2250
 drug metabolism analyses, **429–441**
 advantages/disadvantages
 in vitro research, 431–432, 431*T*
 in vivo research, 432–433, 433*T*
 boron-11 magnetic resonance spectroscopy (^{11}B NMR), 429*T*, 430–431
 carbon-13 magnetic resonance spectroscopy (^{13}C NMR)
 characteristics, 429*T*, 430
 recent research, 436, 438*F*
 in vivo research, 438*F*
 fluorine-19 magnetic resonance spectroscopy (^{19}F NMR)
 characteristics, 429, 429*T*
 recent research, 433–439, 434*F*, 435*F*, 436*F*
 in vitro research, 431–432
 in vivo research, 433–439, 436*F*
 hydrogen-1 magnetic resonance spectroscopy (^1H NMR)
 characteristics, 429*T*, 430
 recent research, 436, 437*F*
 in vitro research, 431–432
 hydrogen-2 magnetic resonance spectroscopy (^2H NMR), 429*T*, 431
 lithium-7 magnetic resonance spectroscopy (^7Li NMR), 429*T*, 430, 438–439
 metabonomics, 2067
 nitrogen-14 nuclear magnetic spectroscopy (^{14}N NMR), 429*T*, 431
 nitrogen-15 nuclear magnetic spectroscopy (^{15}N NMR), 429*T*, 431
 oxygen-17 magnetic resonance spectroscopy (^{17}O NMR), 429*T*, 431
 phosphorus-31 magnetic resonance spectroscopy (^{31}P NMR)
 characteristics, 429*T*, 430
 recent research, 438, 439*F*, 440*F*
 platinum-195 magnetic resonance (^{195}Pt NMR) spectroscopy, 429*T*, 431
 electron magnetic resonance imaging (EMRI), **510–517**
 anti-Helmholtz coils, 512*F*
 background information, 510
 basic concepts
 general discussion, 511
 modulated magnetic field gradients, 511
 projection reconstruction methods, 511
 spatial imaging, 511, 513*F*
 spectral-spatial imaging, 511, 513*F*
 high-field imaging, 514
 L-band imaging, 513–514, 514*F*
 Overhauser imaging, 515–517, 516*F*
 radiofrequency imaging, 514–515
 spin probes, 510
 X-band imaging, 511–513, 512*F*, 513*F*
 fluids in rocks, **1630–1637**
 background information, 1630
 flow velocity and diffusion measurements
 analysis results, 1635*F*
 methodology, 1634–1635, 1635*F*
 laboratory applications
 resolution factors, 1632
 standard imaging sequence, 1631–1632, 1631*F*
 stray field imaging (STRAFI), 1632
 three-dimensional Fourier transform (3D FT) imaging, 1632
 laboratory measurements
 cement paste analysis, 1634, 1634*F*
 chemical shift imaging, 1632, 1633*F*
 fluid saturation, 1632
 mud filtration, 1633–1634
 porosity, 1632
 relaxation times, 1632–1634
 surface wettability, 1633, 1633*F*
 oil well logging
 logging applications, 1636–1637
 logging tools, 1635–1636, 1636*F*
 relaxation properties
 Carr–Purcell pulse sequence, Meiboom–Gill modification (CPMG), 1631
 surface effects, 1630–1631
 susceptibility contrast, 1631
 fluorine-19 magnetic resonance spectroscopy (^{19}F NMR), **645–653**
 applications, 652–653
 biomedical applications, 1111, 2099*T*, 2104–2105, 2104*F*, 2105*F*
 cell research, 220
 characteristics, 213*T*, 429*T*, 645
 chemically induced dynamic nuclear polarization (CIDNP), 318, 318*T*
 chemical shift
 anisotropic characteristics, 648
 coupling constants, 648–649
 effective nuclear charge dependence, 647, 647*F*
 general discussion, 645
 isotope effects, 646, 646*F*
 long-range coupling constants, 651, 651*F*, 652*F*
 one-bond coupling constants, 649, 649*F*, 649*T*
 referenced to CFCl_3 , 646*T*, 907–910*T*
 solvent dependence, 646
 substituent/structure dependence, 647–648, 648*F*
 temperature dependence, 646, 646*F*
 two-bond coupling constants, 649–650
 vicinal coupling constants, 650–651, 650*T*
 drug metabolism analyses, 429, 431–432, 433–439, 434*F*, 435*F*, 436*F*
 experimental aspects, 645
 high-resolution NMR spectroscopy, **905–916**
 abundant spin determination methods, 911
 chemical shifts, 907–910*T*
 cross polarization (CP) analyses, 912
 dilute spin determination methods, 911–913, 912*F*
 general discussion, 905
 inorganic solids analyses, 913
 lipid bilayer analyses, 914–915, 915*F*

- liquid crystal analyses, 914–915
 nuclear spin properties, 905–906, 906*T*
 organic molecule analyses, 913
 oriented sample analyses, 913
 peptides and proteins, 915
 polymer and rubber analyses, 914
in vivo applications, 1100*T*
 isotopic labelling, 1244–1245, 1245*F*
 liver research, 1103–1104, 1103*F*
 membrane studies, 1504, 1505*T*,
 1506*F*
 nuclear properties, 645*T*
 nuclear spin properties, 905–906, 906*T*
 plant science applications, 2184*T*, 2187
 protein–ligand interactions, 1394
 relaxation times, 652
 stray field imaging (STRAFI), 1649–1650,
 1650*F*, 1651*T*
 two-bond coupling constants
 $^2J(^{13}\text{C}-\text{X}-^{19}\text{F})$, 649–650
 $^2J(^{19}\text{F}-\text{X}-^{19}\text{F})$, 650
 $^2J(^1\text{H}-\text{X}-^{19}\text{F})$, 649–650
 $^2J(\text{X}, ^{19}\text{F})$, 649–650, 650*T*
- food and nutritional science applications,
 671–679
 compositional analyses
 high-resolution NMR spectroscopy,
 677, 678*T*
 low-resolution NMR spectroscopy,
 678, 678*T*
 diffusion studies
 cellular plant systems, 676
 food emulsions, 676
 gels and starch-based systems, 675–676
 microstructural considerations,
 675–676
 food processing
 drying studies, 672–673, 673*T*
 freeze-drying studies, 673
 freezing studies, 673, 673*T*
 general discussion, 672–673
 heat transport, 673
 quality factor imaging, 674, 674*T*
 rehydration studies, 673, 673*T*
 temperature mapping, 673, 673*T*
 food structure analyses, 667*F*, 668*F*,
 669–670
 relaxation studies
 aqueous solutions, gels, and glasses,
 677
 microstructural considerations,
 676–677
 rheological studies
 extrusion studies, 675
 food materials, 675*T*
 general discussion, 674–675
 quality assurance measurements, 675
 shear-induced nonrheological changes,
 674–675
 spatially resolved applications
 flow imaging, 674–675, 675*T*
 food processing, 672–673
 general discussion, 671
 quality factor imaging, 671–672, 672*T*
 rheological studies, 674–675, 675*T*
 whole plant imaging, 671, 672*T*
- functional magnetic resonance imaging
 (fMRI), 741–748
 background information, 741
 basic concepts
 excitation–reception processes,
 742–743, 744*F*
 general discussion, 741–744
 hardware schematic diagram, 742*F*
 net magnetization, 741–742, 743*F*
 blood oxygenation level-dependent
 (BOLD) fMRI, 744–746, 745*F*
 clinical applications, 1611, 1613*F*
 experimental results
 data analysis, 746–747
 data collection and processing,
 746–747
 data imaging and interpretation, 747,
 747*F*
 future research areas, 747–748
 imaging equipment, 741*F*
 gallium-71 magnetic resonance spectroscopy
 (^{71}Ga NMR)
 chemical shifts, 795–796, 795*T*, 796*F*
 nuclei characteristics, 786*T*
 historical background, 1441*T*, 1442
 hydrogen-1 magnetic resonance
 spectroscopy (^1H NMR)
 biofluid analyses, 128–141
 amniotic fluid, 129*T*, 139–140
 aqueous humor, 129*T*, 140

Curie-point pyrolysers, 2302–2304,
2304*F*, 2304*T*, 2305*F*, 2306*F*, 2309*F*
- direct probe pyrolysers, 2301–2302
- general discussion, 2301–2302
- laser microprobe mass analyser
(LMMA), 2302*F*, 2305
- linear programmed thermal
degradation mass spectrometry
(LPTDMS), 2302, 2302*F*
- schematic diagram, 2301*F*
- tandem mass spectrometry (MS–MS),
2302*F*
- temperature rise time (TRT), 2302,
2302*F*, 2304*T*
- temperature time profile (TTP), 2302
- total heating time (THT), 2302, 2302*F*
- analytical systems
characteristics, 2305–2308
experimental configurations, 2306*F*,
2307*F*, 2308*F*
- field desorption (FD) pyrolysis setup,
2307*F*
- pyrolysis vapour generator, 2308*F*
- applications
bacteria, 2311–2312, 2311*F*
- natural products, 2308–2311, 2309*F*,
2310*F*
- synthetic polymers, 2312–2313, 2312*F*
- data analysis and reproducibility, 2308,
2308*T*, 2309*F*
- general discussion, 2301
- instrumentation, 2303*F*
- quadrupole ion trap mass spectrometer,
1165–1173
background information, 1165, 1456
- basic concepts, 1165–1166
- chemical ionization (CI), 1172–1173
- collision-induced dissociation (CID),
1172
- electrodes, 1166*F*
- general discussion, 1173
- historical background, 1166–1167

- mass spectrometry (MS) (*continued*)
 ion molecule reactions, 1172–1173
 ion trajectory stability regions, 1169, 1169*F*, 1170*F*
 ion trap operation theory
 general discussion, 1167–1168
 Mathieu equation, 1168
 quadrupole field, 1167–1168
 stretched ion trap, 1168–1169
 laser ablation–inductively coupled plasma–mass spectrometry (LA–ICP–MS), 1265–1266
 metabonomic studies, 1669
 operation as mass spectrometer, 1171–1172, 1171*F*
 parabolic trapping potential, 1167*F*
 potential surface, 1170*F*
 protein and peptide analyses, 2055*T*, 2281–2282
 resonant excitation, 1170–1171
 scan function, 1172, 1172*F*
 schematic diagram, 1166*F*
 secondary ion mass spectrometry (SIMS), 2507–2508
 secular frequencies, 1169–1170, 1170*F*
 tandem mass spectrometry (MS–MS), 1172
 trapping potential well, 1167, 1168*F*
 quadrupole mass spectrometers, **2315–2324**
 applications
 gas chromatography–mass spectrometry (GC–MS) analyses, 2319–2320
 inductively coupled plasma–mass spectrometry (ICP–MS), 2322–2324, 2323*F*
 liquid chromatography–mass spectrometry (LC–MS) analyses, 2320–2321, 2320*F*
 residual gas analysis, 2319
 tandem mass spectrometry (MS–MS), 1676–1677, 1677*F*, 2321–2322, 2321*F*, 2322*F*, 2323*F*
 general discussion, 2315
 historical background, 2315–2316
 operation principles
 field imperfections, 2318–2319
 fringing fields, 2317–2318, 2318*F*
 perfect field concept, 2316
 performance limitations, 2319, 2319*F*
 stability zones, 2316, 2317*F*
 transmission factors, 2317–2318, 2317*F*, 2318*F*
 schematic diagram, 2315*F*
 triple-quadrupole instruments, 1676–1677, 1677*F*, 2321–2322, 2321*F*, 2322*F*, 2323*F*
 secondary ion mass spectrometry (SIMS), **2504–2510**
 analytical characteristics, 85*T*, 1308*T*
 background information, 2504
 basic concepts, 2505–2506
 data analysis, 2509
 depth profile diagram, 2505*F*
 historical background, 566
 imaging mass spectrometry (IMS), 2504–2505, 2505*F*
 instrumentation, 2506
 ion sources
 atomic ion sources, 2506–2507
 cluster ion sources, 2507
 general discussion, 2506–2507
 mass analyzers, 2507–2508
 matrix-assisted laser desorption/ionization (MALDI) mass spectrometry, 1446, 1450*F*
 matrix-enhanced SIMS, 2508
 metabonomic studies, 1668
 multidimensional imaging techniques, 2509, 2509*F*
 nuclear materials analysis, 90
 polarization methods, 2508
 research developments, 2509
 sensitivity enhancement, 2508
 spatial resolution, 1447
 selected-ion flow tube (SIFT) technique, **2518–2530**
 applications
 atmospheric ion chemistry, 2520–2521, 2521*F*, 2522*F*
 interstellar ion chemistry, 2521–2526, 2522*F*, 2523*F*
 trace gas analysis, 2523*F*, 2524*F*, 2525*F*, 2526–2529, 2526*F*, 2527*F*, 2528*F*
 basic concepts
 apparatus diagram, 2519*F*, 2523*F*
 general discussion, 2518–2520
 ion–molecule reactions, 2519*F*
 rate coefficient calculations, 2519, 2520*F*
 general discussion, 2518
 ion–molecule reactions, 1149, 2519*F*
 spectrometers
 components, 1455
 historical background, 1453*F*, 1454–1455, 1454*F*, 1455*F*
 metabonomic studies
 general discussion, 1668–1669
 high-mass resolution instruments, 1669
 low-mass resolution instruments, 1668–1669
 sector instruments
 analyser, 1454*F*, 1455*F*, 1456
 collector, 1456
 ion cyclotron resonance (ICR) mass spectrometer, 1456
 ion sources, 1455–1456
 ion trap, 1456
 quadrupole mass spectrometer, 1456
 time-of-flight (TOF) mass spectrometers, 1456
 static secondary ion mass spectrometry (SSIMS), 1307–1309, 1308*T*
 statistical theory, **2689–2695**
 basic model
 characteristics, 2689
 photoelectron–photoion coincidence (PEPICO) measurements, 2689, 2690*F*
 potential energy curves, 2690*F*
 complex models
 bottlenecks, 2693
 effective number of states, 2694
 general discussion, 2693
 microcanonical variational transition state (VTST), 2693
 nonadiabatic reactions, 2694
 orbiting transition state phase space theory (OTS/PST), 2694
 statistical adiabatic channel model (SACM), 2693–2694
 transition state switching, 2693
 general discussion, 2694–2695
 kinetic energy release distributions (KERDs), 2694
 phase space
 basic concepts, 2689–2691
 initial condition randomness, 2691, 2692*F*
 intramolecular vibrational energy redistribution (IVR), 2691, 2692*F*
 practical calculations, 2692–2693
 RRKM–QET equation, 2692
 transition state, 2691–2692, 2692*F*
 stereochemical analyses, **2696–2707**
 background information, 2696
 biopolymer conformation studies, 2706
 chiral recognition, 2705–2706
 hydrogen transfer
 cycloalkanol dehydration, 2698–2699, 2699*F*
 cycloalkylidene acetates, 2699–2700, 2699*F*
 diester MH⁺ ion-related alcohol elimination, 2700, 2701*F*, 2702*F*
 McLafferty rearrangements, 2700, 2700*F*
 ion–molecule reactions, 2704–2705, 2706*F*
 kinetic considerations
 anchimeric assistance, 2701–2703, 2704*F*, 2705*F*
 general discussion, 2697–2699
 hydrogen transfer, 2698–2699
 retro-Diels–Alder (RDA) fragmentation, 2700–2701, 2703*F*, 2704*F*
 stereoelectronic effects, 2703–2704, 2705*F*, 2706*F*
 thermochemical considerations
 chemical ionization (CI), 2696–2697, 2696*F*, 2697*F*, 2698*F*
 electron ionization (EI), 2696
 surface-induced dissociation (SID), **2763–2777**
 tandem mass spectrometry (MS–MS), **1675–1681**
 applications
 charge reversals, 1754*F*
 fundamental research, 1679
 general discussion, 1679
 (M–H)⁺ species fragmentation, 1748*F*, 1750*F*, 1751*F*, 1752*F*
 peptide sequencing research, 1680
 quantitative bioanalysis, 1680

- structurally related compound studies, 1679–1680, 1680*F*
- structure elucidation studies, 1679
- background information, 1675, 2778
- basic concepts, 984–985, 1675–1676
- biochemical applications, 2057
- chromatographic analyses, 314, 314*F*
- collision-induced dissociation (CID), 2763–2764, 2763*F*
- fast atom bombardment, 570–572
- instrumentation
- Fourier transform–ion–cyclotron resonance (FT–ICR) instruments, 313, 1448, 1448*F*, 1450*F*, 1678–1679, 2090, 2091*F*
 - ion identification strategies, 1450–1451
 - ion-trap instruments, 313, 1677–1678, 1677*F*
 - liquid chromatography–tandem mass spectrometry (LC–MS/MS), 1451
 - sector instruments, 313, 1521–1522, 1676, 1677*F*, 2517
 - time-of-flight (TOF) instruments, 313, 1678, 1678*F*
 - triple–quadrupole instruments, 1676–1677, 1677*F*, 2321–2322, 2321*F*, 2322*F*, 2323*F*
- isotopic labelling, 1242–1243
- multiphoton excitation, 1688–1689, 1689*F*
- nucleic acids and nucleotides, 1989
- pyrolysis mass spectrometry (Py–MS), 2302*F*
- quadrupole ion trap mass spectrometer, 1172
- scan modes, 314*T*
- schematic diagram, 985*F*, 1522*F*
- surface-induced dissociation (SID), 2763–2764, 2763*F*
- time-of-flight (TOF) mass spectrometers, 2855
- tandem quadrupole (QQ) mass spectrometry, 2778–2780, 2779*F*
- thermal ionization mass spectrometry (TIMS)
- analytical characteristics, 85*T*
 - bullet lead analysis, 89
 - isotope ratio studies, 760, 992, 1227–1228
 - isotopic anomalies, 416
 - nuclear materials analysis, 90
- thermospray ionization, **2844–2850**
- applications, 2848–2849
 - basic concepts, 2844
 - future research areas, 2849

 STOCSY-type experiments, 2062–2063, 2063*F*
 Metabolomics Standards Initiative (MSI), 5–8
 metachromasy, 449
 metal–carbon–hydrogen complexes, 1691–1692, 1691*F*
 metallomics, **183–184**
 applications
 extrinsic metal tag determinations, 184
 intrinsic bioelement determinations, 183
 characteristics, 183
 metalloporphyrin analyses, 2429–2432, 2431*F*, 2432*F*
 metalloproteins, 123
 metal surface selection rule (MSSR), 2814, 2814*F*
 metastable exchange optical pumping (MEOP) technique, 973
 metastable ions, **1521–1526**
 characteristics, 1457, 1521–1522
 collision-induced dissociation (CID), 1523–1524
 fragment ions, 1524–1525
 ion production, 1465
 ion structure analyses, 1524–1525, 1525*F*

- isotopic labelling, 1525–1526
- metastable peaks
characteristics, 1457*F*, 1522–1523
composite peaks, 1524*F*
flat-topped peaks, 1539*F*
Gaussian peaks, 1539*F*
isotopic labelling, 1525–1526
rate constant–internal energy
relationship, 1523*F*
neutral species losses, 1526
- meteorites
Allende meteorite, 416–417, 417*F*, 419*F*
Fourier transform Raman spectroscopy,
739–740
isotopic compositions, 416*F*
Murchison meteorite, 417, 417*F*
refractory inclusions, 415
Richardton meteorite, 416*F*
SNC meteorites, 421
X-ray diffraction (XRD) studies, 1051–1052,
1052*F*
- methamphetamines, 694*T*
- methane (CH₄)
coherent anti-Stokes Raman spectroscopy
(CARS), 1917–1924, 1919*F*
enthalpy data, 1456*T*
Fourier transform infrared (FTIR)
spectroscopic surface studies,
2816–2817, 2816*F*, 2817*F*
gas-phase acidities, 2847*T*
interstellar and circumstellar molecules,
1070*T*
interstellar ices, 1070–1072, 1071*F*, 1072*T*
photoacoustic spectroscopy (PAS) analyses,
2143*F*
proton affinities, 2847*T*
- Methanobacterium thermoautotrophicum*, 1886
- methanol (CH₃O)
chemical shift experiments, 365
gas-phase acidities, 2847*T*
hydrogen-1 magnetic resonance
spectroscopy (¹H NMR), 750*F*
infrared (IR) spectroscopic analyses, 962*F*
interstellar and circumstellar molecules,
1070*T*
interstellar ices, 1070–1072, 1071*F*, 1072*T*
labelled material studies, 1249–1252,
1250*F*
photoacoustic spectroscopy (PAS) analyses,
2143*F*
proton affinities, 2847*T*
quantitative NMR (qNMR) analyses, 2336*F*
selected-ion flow tube (SIFT) analysis,
2525*F*, 2528*F*, 2529
tin-119 nuclear magnetic resonance (¹¹⁹Sn
NMR) spectroscopy, 802*F*
wavelength cutoffs, 2034*T*
xenon-129 magnetic resonance spectroscopy
(¹²⁹Xe NMR), 2951*T*
zero kinetic energy (ZEKE) photoelectron
spectroscopy, 3045–3046, 3046*F*
- methionine
hydrogen-1 magnetic resonance
spectroscopy (¹H NMR), 131–135*T*
(M–H)⁺ species fragmentation, 1750*T*
Raman spectroscopic analysis, 120
- α -methoxy- α -trifluoromethylphenylacetic acid
(MTPA), 485–487, 485*F*
methoxybenzoic acid, 1486*T*
methyladipic acid, 1486*T*
methylamine, 131–135*T*, 2847*T*
methylaziridine, 2890
methyl chloride (CH₃Cl), 2951*T*
methylcyclohexanone, 2360, 2381, 2889
methylcyclopentanone, 2360, 2381
methylene carbons, 368–369
methylene (CH₂), 105*F*, 106, 106–107
methylene iodide (CH₂I₂), 2951*T*
methylenoxonium radical cation, 1159–1161,
1160*F*
methylguanadine, 131–135*T*
methylhydroxybutyric acid, 1486*T*
methyl iodide (CH₃I), 1560–1561, 1917,
1919*F*, 2951*T*
methyl isothiocyanate, 1796*T*
methylmalonic acid (MMA), 1485–1489,
1485*F*, 1486*F*, 1486*T*
methyl mandelate, 2890–2891
methylnicotinamide, 131–135*T*
methyl nitrate, 1796*T*
methyl orange, 449
methyloxirane, 2890
methylumbelliferone, 636*T*
methyl vinyl ketone, 606*F*
methyl viologen, 2621–2622, 2630–2632,
2630*F*, 2631*F*
(M–H)⁺ species fragmentation
amino acid residue side-chain cleavage,
1750*T*
aspartic acid-backbone cleavage,
1752*F*
characteristics, 1748–1750
cleavage mechanisms, 1749*F*, 1750*F*
collision-induced tandem mass (MS–MS)
spectra, 1748*F*, 1750*F*, 1751*F*,
1752*F*
peptide-backbone cleavage, 1751*F*
- Michelson interferometers
basic optics, 1200*F*
characteristics, 885–886
collimated molecular beams, 887–888
extended radiation source, 887–888, 887*F*
interference record, 886*F*
lineshape function, 888*F*
optical arrangement, 885*F*
schematic diagram, 886*F*
wide band continuous spectrum, 886*F*
- Microarray Gene Expression Databases
(MGED), 4
- microcanonical rate constant
experimental techniques, 1128
microsecond time window, 1128
millisecond time window, 1129, 1129*F*
nanosecond time window, 1128
photoelectron–photoion coincidence
(PEPICO) spectroscopy, 1128, 1129*F*
microfluorescence (MXRF) analysis, 3002,
3004, 3008*T*
microfluorometry, 621
micro-proton-induced X-ray emission
(microPIXE) analysis, 2296–2297,
2298*T*
- microscopy
compound microscopes
general discussion, 2350–2351
lenses, 2350–2351, 2350*F*, 2351*F*
schematic diagram, 2350*F*
spatial resolution, 2351
magnetic force microscopy (MFM),
1415–1425
basic concepts, 1415, 1415*F*
image formation, 1417–1419, 1418*F*
instrumentation, 1419–1420
operation modes, 1415–1417, 1416*F*
tips
CantiClever concept design,
1424–1425, 1424*F*
coatings, 1423–1424
fabrication methods, 1422–1423,
1423*F*
ideal shape, 1422, 1422*F*
tip planes, 1424–1425, 1424*F*
tip–sample distance control, 1420–1422,
1421*F*
tip transfer functions, 1418, 1419*F*, 1419*T*
- magnetic resonance microscopy (MRM),
1654–1662
applications
general discussion, 1660–1662
neuroanatomical studies, 1661*F*
transport mechanisms, 1661*F*
experimental strategies
basic concepts, 1658–1660
encoding techniques, 1660, 1661*F*
hyperpolarization, 1658–1659
magnetic fields, 1659
parahydrogen-induced polarization
(PHIP), 1659, 1660*F*
signal averaging methods, 1658
single-point imaging (SPI), 1660
spin-exchange optical pumping (SEOP)
technique, 1659
image acquisition principles, 1654–1656,
1655*F*, 1657*F*
image contrast techniques
basic concepts, 1656–1658
plant anatomy, 1658*F*
polarization images, 1659*F*, 1660*F*
water flow velocity image, 1658*F*
- microspectroscopy, 2349–2357
basic concepts, 2349–2350, 2349*F*
compound microscopes
general discussion, 2350–2351
lenses, 2350–2351, 2350*F*, 2351*F*
schematic diagram, 2350*F*
spatial resolution, 2351
instrumentation
compound microscopes, 2350–2351,
2350*F*
detectors, 2352, 2352*T*
general discussion, 2350
light sources, 2350
spectrometers, 2351–2352
mapping and imaging techniques, 2349*F*
sampling considerations, 2356–2357
resolution factors
general discussion, 2457
near-field techniques, 2457

- microscopy (*continued*)
 x - y plane, 2457
 z plane, 2457
scanning electron microscopy (SEM), 759–760
scanning near-field optical microscopy (SNOM)
aperture SNOM (a-SNOM), 2461, 2461*F*
basic concepts, 2461
scattering SNOM (s-SNOM), 2462
scanning probe microscopy, **2464–2472**
analytical methodology, 2473
applications, **2473–2480**
biological systems, 2476
future research areas, 2479–2480
metal analyses, 2475–2476, 2477*F*
polymer analyses, 2476, 2478*F*
semiconductor surface
characterizations, 2475, 2475*F*
single molecule studies, 2476–2479, 2478*F*, 2479*F*
superconductor analyses, 2476
atomic force microscopy (AFM)
basic concepts, 2470, 2470*F*, 2473–2474, 2474*F*, 2485
elastic properties analyses, 2486
future research areas, 2479–2480
general discussion, 2481
high-resolution operations, 2485–2486, 2486*F*
single molecule studies, 2478, 2478*F*, 2479*F*
Van der Waals–Pauli interactions, 2485
basic concepts, **2481–2487**
atomic force microscopy (AFM), 2470, 2470*F*, 2473–2474, 2474*F*, 2485
general discussion, 2481
near-field scanning optical microscopy (NSOM), 2470–2471, 2474, 2474*F*, 2486
scanning tunnelling microscopy (STM), 2473, 2481–2482, 2481*F*, 2482*F*, 2487
combined surface plasmon resonance microscope and scanning probe microscope, 2803, 2803*F*
general discussion, 2464
instrumentation, 2473
near-field scanning optical microscopy (NSOM)
basic concepts, 2470–2471, 2474, 2474*F*, 2486
biological systems, 2471*F*, 2476
future research areas, 2479–2480
general discussion, 2481
polymer analyses, 2471*F*, 2476, 2478*F*
semiconductor surface
characterizations, 2475, 2475*F*
single molecule studies, 2476–2478
scanning tunnelling microscopy (STM)
barrier height spectroscopy, 2467, 2467*F*
basic concepts, 2473, 2474*F*, 2481–2482, 2481*F*, 2482*F*
experimental methods, 2464–2466
future research areas, 2479–2480
general discussion, 2481
inelastic electron tunnelling spectroscopy, 2467–2468, 2467*F*, 2468*F*, 2469*F*, 2821
instrumentation, 2468
local current–voltage (I – V) measurements, 2466, 2466*F*
metal analyses, 2475–2476, 2477*F*
photon emission, 2468
scanning tunnelling spectroscopy (STS), 2466
semiconductor surface
characterizations, 2475, 2475*F*
single molecule studies, 2476–2479
superconductor analyses, 2476
voltage-dependent imaging, 2464–2466, 2465*F*
tip–sample tunnelling gap, 2464*F*, 2467*F*
scanning transmission ion microscopy (STIM), 2297–2298, 2298*F*
surface plasmon resonance (SPR) microscopy
basic concepts, 2800–2802, 2801*F*
combined surface plasmon resonance microscope and scanning probe microscope, 2803, 2803*F*
image quality improvement processes, 2802–2803, 2802*F*
instrumentation, 2801–2802, 2802*F*
total internal reflectance fluorescence (TIRF) microscopy
cell biology applications, 2460–2461
evanescent wave, 2458*F*, 2459*F*
general discussion, 2457–2458
implementation configurations
general discussion, 2460
prism-based TIRF, 2460, 2460*F*
prismless/objective TIRF, 2460, 2460*F*
intensity considerations, 2458–2460, 2459*F*
penetration depth, 2458
polarization considerations, 2458–2460, 2459*F*
single-molecule detection, 2461
surface plasmons, 2805, 2812
total internal reflection calculation, 2458, 2458*F*
microsecond time window, 1128
microspectrofluorimetry
biological applications
Alamar blue assays, 640, 641*T*, 642*F*, 643*F*
calcein assays, 640, 641*T*, 643*F*
cell–cell adhesion assays, 642
cell viability studies, 639–640, 641*T*, 642*F*
chloromethyl fluorescein diacetate (CMFDA) assays, 642
dihydrodichlorofluorescein diacetate (H2DCFDA) assays, 640–641, 643*F*
general discussion, 638–640
intracellular sulphhydryl level assessments, 641–642
oxidative stress assessments, 640–641
general discussion, 621, 642
microspectroscopy, **2349–2357**
basic concepts, 2349–2350, 2349*F*
instrumentation
compound microscopes
general discussion, 2350–2351
lenses, 2350–2351, 2350*F*, 2351*F*
schematic diagram, 2350*F*
spatial resolution, 2351
detectors, 2352, 2352*T*
general discussion, 2350
light sources, 2350
spectrometers, 2351–2352
mapping and imaging techniques, 2349*F*
microspectrofluorimetry
biological applications
Alamar blue assays, 640, 641*T*, 642*F*, 643*F*
calcein assays, 640, 641*T*, 643*F*
cell–cell adhesion assays, 642
cell viability studies, 639–640, 641*T*, 642*F*
chloromethyl fluorescein diacetate (CMFDA) assays, 642
dihydrodichlorofluorescein diacetate (H2DCFDA) assays, 640–641, 643*F*
general discussion, 638–640
intracellular sulphhydryl level assessments, 641–642
oxidative stress assessments, 640–641
general discussion, 621, 642
sampling considerations, 2356–2357
microwave-optical double resonance (MODR) spectroscopy, 1542
microwave region, 451*F*, 455
microwave spectroscopy, **1527–1536**, **1537–1543**
applications
analytical research areas, 1542–1543
atmospheric transmissions, 1532–1533, 1533*F*
electromagnetic radiation studies, 1542
general discussion, 1527
hyperfine structure determinations, 1528*F*, 1541
internal rotation studies, 1542
interstellar molecules, 1533–1536, 1534*T*, 1535*F*, 1536*F*, 1542
molecular electric dipole moments, 1541
molecular parameter determination, 1530–1532, 1532*F*
pollutant analyses, 1532–1533
radioastronomy, 1533–1536, 1535*F*, 1536*F*
rotational spectra
geometrical structure, 1529–1530
rotational constants, 1529–1530, 1531*F*
spectral measurements, 1531*F*
spectral measurements
basic concepts, 1527–1529
collisional broadening parameters, 1528, 1530*F*
hyperfine structure determinations, 1528*F*
phenol–water complex, 1529*F*
propynylidene (C_3H), 1529*F*
rotational spectra, 1531*F*
trioxane, 1528*F*

- structure determinations, 1541
- weakly bound molecules, 1542
- background information, 1537
- basic concepts, 1067–1070, 1540–1541
- characteristics, 1537–1538
- far-infrared spectra, 1069*F*
- ground-based line surveys, 1068*F*
- identified molecular species, 1070*T*
- instrumentation
 - backward wave oscillators (BWOs), 1538

- multidimensional (nD) NMR (*continued*)
 basic concepts
 heteronuclear 3D NMR, 1722–1724, 1724*F*, 1725*F*
 HNCO spectra, 1723–1724, 1725*F*, 2276*F*
 homonuclear correlation spectrum, 1722, 1723*F*
 spectral collection sequences, 1721–1722, 1722*F*
 biological applications, 1721
 data collection methods
 filter diagonalization method (FDM), 1734
 free induction decay (FID), 1734
 G-matrix Fourier transform (GFT) NMR, 1734–1736, 1735*F*
 maximum entropy method (MEM), 1734
 projection reconstruction methods, 1736, 1736*F*
 three-dimensional (3D) NMR, 1734
 historical background, 1440–1441
 peptide and protein orientation studies, 1508, 1508*F*, 1725*F*
 pulse sequences
 absolute value versus phase sensitive two-dimensional (2D) spectra, 1850
 coherence pathway selection, 1850–1852, 1851*F*, 1854*T*
 general discussion, 1849–1850
 gradient pulse sequences, 1852
 two-dimensional nuclear magnetic resonance (2D NMR) spectroscopy, 1849–1850, 1849*F*, 1850*F*, 1851*F*, 1851*T*
 multidimensional protein identification technology (MUDPIT), 2282
 multidimensional spectroscopy, 248
 multifrequency electron paramagnetic resonance (EPR), 523–524, 524*T*
 multiphoton excitation, **1682–1694**
 anion photoelectron spectroscopy, 1683*F*, 1690–1691, 1691*F*
 chemical trace analyses, 1692–1694, 1694*F*
 excitation schemes, 1682–1683, 1683*F*
 experimental setups, 1683–1685, 1684*F*
 general discussion, 1682
 laser desorption analyses, 1692, 1693*F*
 mass selective ion spectroscopy, 1683*F*, 1689–1692, 1690*F*
 multiphoton dissociation–tunable laser ion fragmentation analyses, 1683*F*, 1686–1689, 1687*F*, 1688*F*, 1689*F*
 resonance ionization spectroscopy, 1682, 1683*F*, 1685–1686, 1685*F*, 1686*F*
 multiphoton spectroscopy
 applications, **1695–1703**
 excited-state species analyses, 1698–1700, 1699*F*, 1700*F*
 general discussion, 1697–1700
 ion imaging, 1702, 1702*F*
 REMPI-photoelectron spectroscopy (PES), 1700–1701, 2165, 3051–3052, 3052*F*
 zero kinetic energy (ZEKE)
 photoelectron spectroscopy, 1701, 1701*F*, 2165*F*, 2166
 basic concepts, 1695–1696, 1695*F*
 double-resonance multiphoton spectroscopy, 1699–1700, 1700*F*
 experimental methods, 1696–1697
 multiphoton selection rules
 basic concepts, 1696
 quantum number, 1697*T*
 spherical tensor components, 1697*T*
 symmetry, 1697*T*
 resonance-enhanced multiphoton ionization (REMPI) analyses
 excited-state species analyses, 1698–1700, 1699*F*, 1700*F*
 experimental methods, 1696–1697
 gas-phase molecular systems, 931–932, 932*F*
 ion imaging, 1556, 1560–1561, 1702, 1702*F*
 kinetic energy measurements, 1697
 multiphoton excitation, 1682, 1683*F*
 REMPI-photoelectron spectroscopy (PES), 1700–1701, 2165, 3051–3052, 3052*F*
 small molecule analysis, 3043
 time-of-flight (TOF) methods, 1696–1697
 zero kinetic energy (ZEKE)
 photoelectron spectroscopy, 1701, 1701*F*
 multiple angle light scattering (MALS), 2080
 multiple linear regression, 2328
 multiple quantum experiments, 208, 1831, 2865, 2866*T*
 multiple quantum filter (MQF), 1108, 1109*F*
 multiple-quantum magic-angle spinning (MQ-MAS), 1831, 2588–2589, 2590*F*
 multiplicative signal correction (MSC), 391
 multivariate statistical methods, **1704–1709**
 artificial neural networks (ANNs), 388*F*, 389, 1496–1497
 basic concepts, 1704–1705
 calibration techniques, 388, 1708
 chemometrics, **386–391**
 calibration techniques
 artificial neural networks (ANNs), 388*F*, 389
 characteristics, 388
 locally weighted regression (LWR), 389, 389*F*, 390*F*
 partial least squares (PLS) analysis, 388*F*, 389
 principal component regression (PCR), 388, 388*F*, 1708
 stepwise multiple linear regressions (SMLR), 388, 388*F*
 calibration transfer, 390–391
 data exploration, 386–388, 387*F*
 general discussion, 386
 multiplicative signal correction (MSC), 391
 pretreatment processes, 391
 raw spectra, 386, 387*F*
 validation methods, 389–390, 390*F*, 391*F*
 classification methods, 1707–1708
 general discussion, 1708–1709
 infrared (IR) spectroscopy, 1496–1497, 1497*F*, 1498*F*
 locally weighted regression (LWR), 389, 389*F*, 390*F*
 metabonomic studies, 1514, 1671–1673
 multiple linear regression, 2328
 nonparametric resampling methods
 bootstrap method, 1707
 crossvalidation techniques, 1707
 resubstitution method, 1706–1707
 partial least squares (PLS) analysis
 chemometrics, 388*F*, 389
 functional magnetic resonance imaging (fMRI), 746–747
 infrared (IR) spectroscopy
 medical applications, 1498, 1499*F*
 microbiological studies, 146
 metabonomic studies, 1514, 1518*F*, 2064, 2064*F*
 microbiological studies, 146
 quantitative analysis, 2328–2329
 preprocessing techniques, 1705–1706
 principal component regression (PCR), 388, 388*F*, 1708
 stepwise multiple linear regressions (SMLR), 388, 388*F*
 muonic X-rays, 3020
 muonium (Mu), 1710–1711, 1711*T*, 1713*F*
 muon spin resonance spectroscopy, **1710–1720**
 advantages/disadvantages
 frequency resolution, 1720
 local probe technique, 1720
 sensitivity factors, 1720
 spin polarization, 1719
 time resolution, 1719–1720
 time window, 1720
 usable field range, 1719
 applications
 hydrogen–muonium (H–Mu) kinetic isotope effects (KIEs), 1716–1719, 1718*T*
 muonium-labelled organic free radicals, 1714–1716, 1714*F*, 1715*F*, 1716*F*, 1717*F*, 1718*F*, 1718*T*
 reaction rate coefficients, 1718*T*
 relative transmission coefficients, 1718*T*
 background information, 1710
 experimental techniques
 avoided-level-crossing muon spin rotation (ALC– μ SR), 1712*F*, 1713
 longitudinal-field muon spin rotation (LF– μ SR), 1712*F*, 1713
 radiofrequency muon spin rotation (RF– μ SR), 1713
 transverse-field muon spin rotation (TF– μ SR), 1711–1713, 1712*F*, 1713*F*, 1714–1716, 1714*F*, 1715*F*, 1717*F*
 zero-field muon spin rotation (ZF– μ SR), 1712*F*, 1713
 positive muons (μ^+)
 basic concepts, 1710–1711
 polarization detection, 1711
 production processes, 1711
 properties, 1711*T*
 Murchison meteorite, 417, 417*F*

muscle research
 carbon-13 magnetic resonance spectroscopy (^{13}C NMR), 1101
in vivo magnetic resonance spectroscopy, 1104
 magnetic resonance imaging (MRI), 1601, 1601*F*
 phosphorus-31 magnetic resonance spectroscopy (^{31}P NMR), 1114–1115
 musculoskeletal imaging, 1607–1608, 1607*F*
 musgravite ($\text{Mg}_2\text{Al}_6\text{BeO}_{12}$), 738–739
 mycotoxins, 680*T*
 myocardial perfusion, 17, 17*F*, 18*F*, 1619–1620, 1620*F*
 myo-inositol
in vivo hydrogen-1 magnetic resonance spectroscopy (^1H NMR), 1078
in vivo proton magnetic resonance spectroscopy (^1H NMR), 1109*F*

N

N-acetyl-aspartate (NAA), 1078
N-acetyl-aspartyl-glutamate (NAAG), 1078
 Nafion/methyl viologen electrodes, 2630–2632, 2630*F*, 2631*F*
 nanosecond time window, 1128
 naphthalene
 chemical shift experiments, 366
 chemical trace analyses, 1694*F*
 reduced hyperfine coupling tensors, 1718*T*
 transverse-field muon spin rotation (TF- μSR), 1715–1716, 1717*F*
 naproxen, 949–950
 narcotics, 736–738
Natronobacterium pharaonis, 125*F*
 natural membranes *see* membrane studies
 natural resins, 24–26, 736, 737*F*
 nearest neighbor (nn) methods, 1708
 near-field scanning optical microscopy (NSOM)
 basic concepts, 2470–2471, 2474, 2474*F*, 2486
 biological systems, 2471*F*, 2476
 future research areas, 2479–2480
 general discussion, 2481
 polymer analyses, 2471*F*, 2476, 2478*F*
 semiconductor surface characterizations, 2475, 2475*F*
 single molecule studies, 2476–2478
 near-infrared (NIR) spectroscopy
 biopharmaceutical research and development, 2665
 calibration regulatory standards, 199*T*
 chemometric methods, 386–391
 calibration techniques
 artificial neural networks (ANNs), 388*F*, 389
 characteristics, 388

 radiofrequency (RF) pulses, 1838,
 1838*F*
- biological applications, 1440–1442, 1721
 biopharmaceutical research and
 development, 2666
- bismuth-209 magnetic resonance (^{209}Bi
 NMR) spectroscopy, 779–784
 applications, 783–784
 chemical shift, 780–782, 782*F*
 experimental aspects, 779–780
 general discussion, 779
 nuclear properties, 779, 780*T*
- boron-11 magnetic resonance spectroscopy
 (^{11}B NMR)
 characteristics, 429*T*
 chemical shifts, 787–790, 788*T*
 drug metabolism analyses, 430–431
in vivo applications, 1100*T*, 1105
 nuclei characteristics, 786*T*
 organylborane compounds, 788–790,
 788*T*
 plant science applications, 2184*T*, 2187
 polyhedral boranes, 790
 stray field imaging (STRAFI), 1651*T*
- bromine-79/81 magnetic resonance (^{81}Br
 NMR) spectroscopy, 771–778
 conducting and semiconducting lattices,
 777
 electric field gradient (EFG), 771–773
 general discussion, 771
 halide-cation interactions, 776–777
 halide-ligand interactions, 776
 nuclear properties, 771*T*
 quadrupolar interactions, 771–773, 772*F*
 residual dipolar coupling, 775
 shielding, 775–776
 spin-1/2 NMR spectra, 2582*T*
 spin-spin couplings, 774–775, 775*T*
- cadmium-113 magnetic resonance
 spectroscopy (^{113}Cd NMR), 2184*T*,
 2187
- calibration regulatory standards, 202*T*
- carbohydrate analyses, 204–211
 carbon-13 magnetic resonance
 spectroscopy (^{13}C NMR)
 carbon-proton/carbon-carbon spin
 couplings, 209
 multidimensional heteronuclear
 analysis, 209, 210*F*
 primary analysis and assignment, 209
 complex carbohydrate identification, 211
 conformational analyses, 209–211, 210*F*
 dynamic processes, 211
 general discussion, 204
 hydrogen-1 magnetic resonance
 spectroscopy (^1H NMR)
 hydroxyl protons, 208–209
 primary analysis and assignment,
 205–206, 205*F*,
 206*F*
 structural reporter groups, 206*T*
 two-dimensional (2D) homonuclear
 analysis, 206–207
 sample preparation, 204–205
 structural analyses, 205, 205*F*
 two-dimensional (2D) homonuclear
 analysis
 COSY-type experiments, 207, 207*F*
 general discussion, 206–207
 homonuclear Hartmann-Hahn
 (HOHAHA) experiments, 208
 multiple quantum experiments, 208
 nuclear Overhauser enhancement
 spectroscopy (NOESY), 208
 RELAY experiments, 208
 rotating frame Overhauser effect
 spectroscopy (ROESY), 208
 TOCSY-type experiments, 208
- carbon-13 magnetic resonance spectroscopy
 (^{13}C NMR)
 analytical methods, 355–364
 attached-proton test (APT), 358–360,
 358*F*, 359*F*
 chemical shift experiments, 361–363,
 361*F*, 362*T*, 363*T*
 distortionless enhancement by
 polarization transfer (DEPT) test,
 359, 359*F*, 360*F*
 general discussion, 355
 heteronuclear decoupling, 356–357,
 357*F*
 insensitive nuclei enhanced by
 polarization transfer (INEPT)
 test, 360
 multiple pulse experiments, 358–360
 nuclear Overhauser effect (NOE),
 357–358, 358*T*
 single-pulse Fourier transform NMR,
 355–356, 356*F*
 spectral assignment tests, 361–363
 structural determinations, 361–363
 two-dimensional nuclear magnetic
 resonance (2D NMR)
 spectroscopy, 360–361, 360*T*,
 361*F*
- biomedical applications, 1109–1110,
 1110*F*, 1111, 2099*T*, 2103–2104
- carbohydrate analyses
 carbon-proton/carbon-carbon spin
 couplings, 209
 multidimensional heteronuclear
 analysis, 209, 210*F*
 primary analysis and assignment, 209
- carbohydrate metabolism
 brain research, 1101–1102
 cardiac studies, 1101
in vivo applications, 1100–1101
 liver research, 1100–1101, 1101*F*
 muscle research, 1101
- carbon-13 cross polarization-magic angle
 spinning nuclear magnetic resonance
 (^{13}C CP-MAS NMR) spectroscopy
 biopolymers, 899–901
 blend polymers, 898–899
 coals/coal products, 904

 carbon-carbon coupling, 370
 carbon-fluorine coupling, 370
 one-bond J_{CH} , 370, 370*T*
 three-bond J_{CH} , 370
 two-bond J_{CH} , 370
- cross polarization (CP) analyses, 894,
 1829, 1831*F*, 2588
- crystal polymorphism
 cortisone acetate, 2241*T*
 disorder dynamics, 2245*F*
 ethyl carbons, 2241*T*
 identification methods, 2238–2240
 mixture identification, 2242*F*
 phase transitions, 2243–2245, 2243*F*,
 2244*F*
 phenobarbital, 2239*F*
 sulfathiazole, 2240*F*
- drug metabolism analyses, 430, 436, 438*F*
 food and nutritional science applications,
 663*T*, 664–665, 678*T*
 glycogen metabolism, 1254*F*

- nuclear magnetic resonance (NMR)
 spectroscopy (*continued*)
 high-power decoupling, 1828–1829, 1831*F*
 high-resolution solid-state NMR, 894–904
 biopolymers, 899–901
 blend polymers, 898–899
 coals/coal products, 904
 cross polarization–magic angle spinning (CP–MAS) NMR, 894
 fibrous proteins, 901–902
 fluoropolymers, 898
 food analyses, 904
 membrane proteins, 902–903, 903*F*
 polyethylene (PE), 894–897, 895*F*, 896*F*, 897*F*
 polyoxymethylene, 898, 898*F*
 poly(vinyl alcohol) (PVA), 897–898, 897*F*
 synthetic polymers, 894–897
 synthetic polypeptides, 899–901, 900*F*, 901*F*, 902*F*
in vivo applications
 biomedical research, 1100*T*
 carbohydrate metabolism, 1100–1101
 cell research, 216–219, 217*F*, 218*F*
 drug metabolism analyses, 436, 438*F*
 lipids, 1102
 whole-body research, 1099–1101
 labelled material studies, 1247–1249, 1248*F*, 1249–1252, 1250*F*, 2273
 lipids
 adipose tissue, 1102
 brain research, 1103
 food and nutritional science
 applications, 678*T*
in vivo applications, 1102
 liver research, 1102–1103
 liquid crystal order parameters, 1354*F*
 magic angle spinning (MAS) NMR
 instrumentation, 1878
 liquid crystal analyses, 1437–1438
 synthetic polymer analysis, 2226–2227, 2226*F*, 2228–2230, 2229*F*, 2230*F*
 tissue extract analyses, 929
 membrane studies, 1504, 1505*T*, 1506*F*, 1507–1508
 nuclei characteristics, 355, 355*T*, 1099*T*
 organic molecule structural analyses, 2723–2727, 2723*F*, 2724*F*, 2727*F*
 plant science applications, 2184–2186, 2184*T*, 2187
 protein and peptide analyses, 2273
 protein–ligand interactions, 1394
 quantitative NMR (qNMR), 2331–2332
 relaxation reagents, 257*F*
 self-decoupling, 2583*F*
 spectral editing pulse sequences, 1846–1847, 1847*F*, 1848*F*, 1848*T*
 spin-1/2 NMR spectra, 2581–2582, 2581*F*, 2582*F*, 2582*T*
 synthetic polymers
 chemical identification, 2223–2224
 cross polarization (CP) analyses, 2228–2230
 dipolar decoupling (DD) analyses, 2228–2230
 dynamic and exchange NMR, 2231–2234, 2234*F*
 high-resolution magic-angle spinning (MAS) investigations, 2226–2227, 2226*F*, 2228–2230, 2229*F*, 2230*F*
 molecular weight determination, 2223–2224
 multidimensional NMR, 2230–2231, 2231*F*
 one-dimensional (1D) MAS method, 2233–2234, 2234*F*
 oriented polymers, 2235–2236
 relaxation studies, 2224–2226, 2225*F*
 separated local field (SLF) analyses, 2230–2231
 sequence analysis, 2224, 2224*F*
 solution-state studies, 2223–2224
 wideline separation (WISE) analyses, 2230–2231, 2231*F*
 cell research, 212–220
 background information, 212–213
 carbon-13 magnetic resonance spectroscopy (^{13}C NMR), 213*T*, 216–219, 217*F*, 218*F*
 fluorine-19 magnetic resonance spectroscopy (^{19}F NMR), 213*T*, 220
 hydrogen-1 magnetic resonance spectroscopy (^1H NMR), 213*T*, 219–220, 219*F*, 220*F*
 hydrogen-2 magnetic resonance spectroscopy (^2H NMR), 213*T*, 220
 large-scale/high-density cell culture procedures, 213–215, 214*F*
 nitrogen-14 nuclear magnetic spectroscopy (^{14}N NMR), 213*T*
 nitrogen-15 nuclear magnetic spectroscopy (^{15}N NMR), 213*T*
 oxygen-17 magnetic resonance spectroscopy (^{17}O NMR), 213*T*, 220
 phosphorus-31 magnetic resonance spectroscopy (^{31}P NMR), 213*T*, 215–216, 215*F*
 potassium-39 magnetic resonance spectroscopy (^{39}K NMR), 213*T*
 sodium-23 magnetic resonance spectroscopy (^{23}Na NMR), 213*T*, 220
 cesium-133 magnetic resonance spectroscopy (^{133}Cs NMR), 678*T*, 2184*T*, 2187
 chemical exchange, 229–237
 basic concepts, 229–230, 229*F*, 1840, 1840*F*
 Bloch equations, 230
 eigenvalues/eigenvectors, 236–237
 fast chemical exchange, 235
 general discussion, 236
 scalar coupled systems, 231–232, 232*F*, 233–234, 235*F*
 slow chemical exchange, 234–235, 236*F*
 time domain considerations, 230–231, 231*F*
 transition probability calculations, 232–233
 chemically induced dynamic nuclear polarization (CIDNP), 317–324
 applications
 biologically relevant molecules, 323–324
 biradical reactions, 322–323
 carbene radical reactions, 323
 complex radical chemical reactions, 321–322
 magnetic resonance parameters studies, 321–322, 322*T*
 molecular dynamics research, 323
 spin dynamics research, 323
 structural chemistry analyses, 321–322, 322*F*
 complex radical chemical reactions, 317
 effect characteristics
 high magnetic fields, 318–320, 319*F*
 low magnetic fields, 320–321
 multiplet effects, 319*F*
 net effects, 319*F*
 multiplet effects, 318
 net effects, 318
 nuclei spin data, 318, 318*T*
 observation techniques, 318
 polarization methods, 967–968, 967*F*, 968*F*
 solid-state photo-CIDNP, 968–969, 969*F*
 technique comparisons, 321
 chemical shift, 253–261
 carbon-13 magnetic resonance spectroscopy (^{13}C NMR), 365–371
 alkanes, 365, 366*T*
 alkenes, 365, 368*T*
 alkynes, 366, 368*T*
 amines, 368
 amino acids, 368
 aromatic hydrocarbons, 366, 369*T*
 carbonyl carbons, 369, 370*T*
 general discussion, 365
 methyl groups, 365, 367*T*
 oxygen-containing compounds, 366–368
 spectral assignment tests, 361–363, 361*F*
 steric correction parameters, 363*T*
 substituent chemical shift parameters, 362*T*
 chiral (LSR) shift reagents
 alkali metal ions, 256–257, 257*F*
 basic concepts, 255–256
 magnetic resonance imaging (MRI)
 contrast agents, 259–261, 260*F*, 1610–1611
 shift reagents, 256*T*
 spectral data, 256*F*, 257*F*
 lanthanide-induced shifts
 basic concepts, 254–255
 causal factors, 255
 shift reagents, 254*T*, 484–485
 spectral data, 254*F*
 paramagnetic interactions, 253–254

 one-bond coupling constants
 $^1J(\text{E}, ^{13}\text{C})$ constants, 806
 $^1J(\text{E}, ^1\text{H})$ constants, 805
 $^1J(\text{E}, \text{transition metal})$ constants, 807
 $^1J(\text{E}, \text{X})$ constants, 806–807
 general discussion, 805

- solid-state nuclear magnetic resonance (NMR) spectroscopy, 809
- vicinal coupling constants
 $^nJ(E,Y)$ constants, 808–809, 808*T*
 relaxation mechanisms, 808–809
- heteronuclear NMR
 d-block metals, **834–843**
 group 13 elements, 785–787
 mercury (Hg), 814
 oxygen (O), 816–818
 platinum (Pt), 813–814
 selenium (Se), 819–821
 sulfur (S), 819
 tellurium (Te), 822
 third transition series metals, **824–833**
 tungsten (W), 812–813
- high-performance liquid
 chromatography–nuclear magnetic resonance (HPLC–NMR) spectroscopy, **946–956**
 continuous-flow detection, 947, 948*F*, 949*F*
 general discussion, 946
 historical background, 946
 limitations, 955–956
 metabolite characterization, 952–955, 953*F*, 954*F*, 955*F*
 operation principles, 947–949
 probe design, 951–952
 schematic diagram, 948*F*
 sensitivity factors, 950–951
 solvent characteristics, 949–950, 950*F*
 stop-flow approach, 947–949
 technical improvements, 946–947
- high pressure studies, **854–864**
 applications
 biochemical studies, 863
 chemical reaction mechanisms, 860*T*, 861–862
 dynamic structure of liquids, 856–858, 858*F*
 molecular solid phase transitions, 859–860, 859*F*
 polymer crystallization kinetics, 860*F*, 861
 spin-lattice relaxation times, 859–860, 859*F*
 supercritical fluids, 858–859, 859*F*
- biochemical applications
 model membranes, 860*T*, 861*F*, 863
 protein denaturation, 862*F*, 863–864, 863*F*
- general discussion, 854
- instrumentation
 general discussion, 856
 performance characteristics, 857*T*
 schematic diagram, 856*F*, 857*F*
 spectral data, 858*F*
 pressure effects, 854–856, 855*F*
 standard equations, 854
- high-resolution NMR spectroscopy
 carbon-13 magnetic resonance spectroscopy (^{13}C NMR), **894–904**
 biopolymers, 899–901
 blend polymers, 898–899
 coals/coal products, 904
 cross polarization–magic angle spinning (CP–MAS) NMR, 894
 fibrous proteins, 901–902
 fluoropolymers, 898
 food analyses, 904
 membrane proteins, 902–903, 903*F*
 polyethylene (PE), 894–897, 895*F*, 896*F*, 897*F*
 polyoxymethylene, 898, 898*F*
 poly(vinyl alcohol) (PVA), 897–898, 897*F*
 synthetic polymers, 894–897
 synthetic polypeptides, 899–901, 900*F*, 901*F*, 902*F*
- fluorine-19 magnetic resonance spectroscopy (^{19}F NMR), **905–916**
 general discussion, 905
 inorganic solids analyses, 913
 lipid bilayer analyses, 914–915, 915*F*
 liquid crystal analyses, 914–915
 nuclear spin properties, 905–906, 906*T*
 organic molecule analyses, 913
 oriented sample analyses, 913
 peptides and proteins, 915
 polymer and rubber analyses, 914
 food and nutritional science applications, 677, 678*T*
- hydrogen-1 magnetic resonance spectroscopy (^1H NMR), **905–916**
 general discussion, 905
 inorganic solids analyses, 913
 lipid bilayer analyses, 914–915, 914*F*
 liquid crystal analyses, 914–915
 nuclear spin properties, 905–906, 906*T*
 organic molecule analyses, 913
 oriented sample analyses, 913
 peptides and proteins, 915
 polymer and rubber analyses, 914
 radiofrequency (RF) field gradients, 2345–2348
- historical background, **1435–1442**
 biological applications, 1440–1442
 developmental milestones, 1436*T*, 1439–1440*T*, 1441*T*
 early experimental research and developments, 1435–1437, 1436*T*
 general discussion, 1435
 liquid-crystal nuclear magnetic resonance (NMR) spectroscopy, 1436*T*, 1437–1438
 magnetic resonance imaging (MRI), 1441*T*, 1442
 multidimensional NMR, 1441
 solid-state nuclear magnetic resonance (NMR) spectroscopy, 1436*T*, 1437–1438
 solution-state nuclear magnetic resonance (NMR) spectroscopy, 1438–1440, 1439–1440*T*
 two-dimensional nuclear magnetic resonance (2D NMR) spectroscopy, 1440–1441
- hydrogen-1 magnetic resonance spectroscopy (^1H NMR)
 biofluid analyses, **128–141**
 amniotic fluid, 129*T*, 139–140
 aqueous humor, 129*T*, 140
 background information, 128
 bile, 129*T*, 139
 blood serum and plasma, 129*T*, 130–136, 130*F*
 cerebrospinal fluid (CSF), 129*T*, 138–139
 digestive fluids, 140
 dynamic interactions, 129–130
 follicular fluid, 129*T*, 139–140
 food and nutritional science, 1513–1514
 metabolites, 131–135*T*
 metabonomic studies, 1513–1514, 2058–2059, 2060*F*, 2061*F*, 2062*F*
 milk, 129*T*, 140
 pathologic cyst fluid, 140–141
 resonance assignments, 129, 131–135*T*
 saliva, 129*T*, 140
 seminal fluids, 129*T*, 139
 solvent suppression methods, 2604
 spectral data, 130*F*
 synovial fluid, 129*T*, 140
 urine, 129*T*, 136–137
 vitreous humor, 140
- biomedical applications, 2099*T*, 2104, **1077–1084**, **1107–1111**
- carbohydrate analyses
 hydroxyl protons, 208–209
 primary analysis and assignment, 205–206, 205*F*, 206*F*
 structural reporter groups, 206*T*
 two-dimensional (2D) homonuclear analysis, 206–207
- cell research, 219–220, 219*F*, 220*F*
 characteristics, 213*T*, 429*T*, 1816
 chemically induced dynamic nuclear polarization (CIDNP)
 biologically relevant molecules, 323–324
 biradical reactions, 322–323
 carbene radical reactions, 323
 complex radical chemical reactions, 321–322
 high magnetic field effects, 318–320, 319*F*
 low magnetic field effects, 320–321
 magnetic resonance parameters studies, 321–322, 322*T*
 molecular dynamics research, 323
 multiplet effects, 318, 319*F*
 net effects, 318, 319*F*
 nuclei spin data, 318, 318*T*
 observation techniques, 318
 spin dynamics research, 323
 structural chemistry analyses, 321–322, 322*F*
 technique comparisons, 321
- cross polarization (CP) analyses, 1829, 1831*F*, 2588
- drug metabolism analyses, 430, 431–432, 436, 437*F*
- drug quality control, 2644, 2647*F*, 2648*F*
- food and nutritional science applications, 663*T*, 664–665, 678*T*, 1513–1514, 1514*F*

- nuclear magnetic resonance (NMR)
 spectroscopy (*continued*)
 gas phase studies, 750*F*, 754, 754*F*
 high-power decoupling, 1828–1829, 1831*F*
 high-resolution NMR spectroscopy, 905–916
 abundant spin determination methods, 906–911, 911*F*
 combined rotation and multiple-pulse spectroscopy (CRAMPS), 906–911, 911*F*
 general discussion, 905
 inorganic solids analyses, 913
 lipid bilayer analyses, 914–915, 914*F*
 liquid crystal analyses, 914–915
 nuclear spin properties, 905–906, 906*T*
 organic molecule analyses, 913
 oriented sample analyses, 913
 peptides and proteins, 915
 polymer and rubber analyses, 914
 proton–proton (^1H – ^1H) decoupling, 911–913, 912*F*
in vivo magnetic resonance spectroscopy, 1085–1098, 1107–1111
 advanced techniques, 1095–1097
 anomalous *J*-modulation, 1097
 artifacts, 1097
 chemical shift displacement, 1097
 chemical shifts, 1086–1087, 1086*F*
 flow and motion factors, 1098
 ghosting, 1097
 image selected *in vivo* spectroscopy (ISIS), 1089
J-coupled techniques, 1095–1097, 1096*F*
 localization sequences, 1087–1090, 1089*F*, 1094*F*
 magnetic resonance spectroscopic imaging (MRSI), 1093–1095, 1094*F*
 methodology, 1087–1090
 modulation sidebands, 1097
 outer-volume suppression (OVS), 1090–1091, 1090*F*, 1094*F*
 postprocessing/quantification methods, 1091–1093, 1092*F*, 1093*F*
 relaxation behavior, 1087, 1088*T*
 sensitivity factors, 1087, 1088*T*
 shimming techniques, 1091
 spectral resolution, 1086–1087
 stimulated echo acquisition mode (STEAM), 1088, 1089*F*
 stimulated echoes, 1098
 three-dimensional (3D) localization by adiabatic selective refocusing (LASER), 1088–1089
 labelled material studies, 1247
 liquid crystals
 molecular dynamics research, 1354–1355
 orientational order parameters, 1353–1354
 rigid molecule structural analysis, 1351–1352, 1351*F*
 magic angle spinning (MAS) NMR
 basic concepts, 1828
 biological applications, 927–929
 food and nutritional science applications, 677
 inorganic structural analysis, 2713*F*
 instrumentation, 1878
 metabonomic studies, 2061
 synthetic polymer analysis, 2226–2227, 2226*F*
 tissue extract analyses, 925–930
 membrane studies, 1504, 1505*T*, 1506*F*
 metabonomic studies, 2058–2059, 2060*F*, 2061*F*, 2062*F*, 2644
 NMR spectrometers, 1878–1879
 nuclear spin properties, 905–906, 906*T*
 organic molecule structural analyses
 general discussion, 2718–2720
 proton chemical shift, 2718–2720, 2719*F*, 2720*F*
 stereochemical assignments, 2721–2723, 2722*F*
 through-bond spin–spin coupling analysis, 2720–2721
 pharmaceutical research and development, 2745–2746, 2746*F*
 plant science applications, 2184–2186, 2184*T*, 2185*F*, 2187
 process analytical technology (PAT), 2655*T*, 2656
 protein and peptide analyses
 historical background, 2272
 orientation studies, 1508–1509
 protein denaturation studies, 862*F*, 863–864
 protein–ligand interactions, 1397–1398
 quantitative NMR (qNMR), 2331–2332, 2333*T*
 stray field imaging (STRAFI), 1649–1650, 1650*F*, 1651*F*, 1651*T*, 1652*F*
 synthetic polymer analysis, 2226–2227
 dynamic and exchange NMR, 2231–2234, 2232*F*, 2233*F*
 high-resolution magic-angle spinning (MAS) investigations, 2226*F*
 low-resolution analyses, 2227–2228, 2227*F*
 spin diffusion NMR, 2234–2235, 2235*F*
 tissue extract analyses, 925–930
 basic concepts, 925
 cellular environment analyses, 927
 future research areas, 929–930
 general discussion, 925
 liver sample spectra, 926*F*, 929*F*
 magic angle spinning (MAS) NMR, 925, 926*F*
 metabonomic studies, 2058–2059
 pulse sequence observing strategies, 927, 928*F*
 sample preparation, 925–926
 hydrogen-2 magnetic resonance spectroscopy (^2H NMR)
 cell research, 220
 characteristics, 213*T*, 429*T*
 chemically induced dynamic nuclear polarization (CIDNP), 318*T*
 drug metabolism analyses, 431
 exchange experiments, 2593*F*, 2594
 food and nutritional science applications, 663*T*, 664–665
in vivo applications, 1100*T*, 1105
 labelled material studies, 1249, 2273
 liquid crystals
 liquid crystalline solutions, 1352
 molecular dynamics research, 1354–1355
 orientational order parameters, 1353–1354, 1354*F*
 phase structure determinations, 1354, 1355*F*
 membrane studies
 advantages/disadvantages, 1505*T*
 general discussion, 1504
 lipid orientational information, 1507–1508
 motion-order amplitude parameters, 1509*F*, 1510*F*
 properties, 1505*T*
 spectral data, 1506*F*
 plant science applications, 2184*T*, 2187
 protein and peptide analyses, 2273
 spin-1/2 NMR spectra, 2582*T*
 synthetic polymer analysis, 2235–2236
 hyphenated nuclear magnetic resonance (NMR), 979–983
 applications, 982
 capillary electrophoresis (CE), 1879–1880
 extended techniques, 980–981, 981*F*
 food and nutritional science applications, 665
 general discussion, 979
 high-performance liquid chromatography (HPLC), 431–432, 979–980, 1879–1880, 2186, 2186*F*
 high-performance liquid chromatography (HPLC)–solid-phase extraction (SPE)–nuclear magnetic resonance (NMR) technique, 980, 981*F*
 mass spectrometry (MS), 2186, 2186*F*
 metabonomic studies, 2062
 multiple chromatographic techniques, 982
 pharmaceutical research and development, 2640, 2643*F*
 sensitivity factors, 981–982, 982*F*
 signal-to-noise ratio (SNR), 982*F*
 image contrast techniques, 1818–1821
 indium-115 magnetic resonance spectroscopy (^{115}In NMR), 786*T*, 796
 inorganic structural analysis, 2708–2717
 background information, 2708
 dynamic processes, 2714, 2714*F*
 magic angle spinning (MAS) NMR, 2710–2711, 2712*F*, 2713*F*
 multinuclear approach
 general discussion, 2708–2709
 iron-57 (^{57}Fe) NMR spectrum, 2710*F*
 nuclei characteristics, 2709*T*

- oxygen-17 (^{17}O) NMR spectrum,
2710*F*, 2711*F*
vanadium-51 (^{51}V) NMR spectrum,
2710*F*
paramagnetic systems, 2716
parameters
 chemical shifts, 2710–2711, 2712*F*,
 2712*T*, 2714*F*
 coupling constants, 2711–2712, 2713*F*,
 2714*T*
 relaxation times, 2712–2714, 2714*T*
polarization transfer methods
 one-dimensional (1D) experiments,
 2715, 2715*F*
 sensitivity enhancement, 2715, 2715*F*
 two-dimensional (2D) experiments,
 2715–2716, 2716*F*
in vivo magnetic resonance spectroscopy,
 1099–1106
 aluminum-27 magnetic resonance
 spectroscopy (^{27}Al NMR), 1100*T*, 1106
 background information, 1099
 biomedical research, 1100*T*
 boron-11 magnetic resonance
 spectroscopy (^{11}B NMR), 1100*T*, 1105
 carbohydrate metabolism
 brain research, 1101–1102
 cardiac studies, 1101
 general discussion, 1100–1101
 liver research, 1100–1101, 1101*F*
 muscle research, 1101
 carbon-13 magnetic resonance
 spectroscopy (^{13}C NMR)
 biomedical research, 1100*T*
 carbohydrate metabolism, 1100–1101
 cell research, 216–219, 217*F*, 218*F*
 drug metabolism analyses, 436, 438*F*
 lipids, 1102
 nuclei characteristics, 1099*T*
 whole-body research, 1099–1101
 drug metabolism analyses, 432–433,
 433*T*
 fluorine-19 magnetic resonance
 spectroscopy (^{19}F NMR), 1100*T*,
 1103–1104, 1103*F*
 general discussion, 1106
 hydrogen-1 magnetic resonance
 spectroscopy (^1H NMR), **1085–1098**,
 1107–1111
 hydrogen-2 magnetic resonance
 spectroscopy (^2H NMR), 1100*T*, 1105
 image selected *in vivo* spectroscopy
 (ISIS), 1089, 1112
 lipids
 adipose tissue, 1102
 brain research, 1103
 general discussion, 1102
 liver research, 1102–1103
 lithium-7 magnetic resonance
 spectroscopy (^7Li NMR), 1100*T*, 1104
 nitrogen-15 nuclear magnetic
 spectroscopy (^{15}N NMR), 1100*T*, 1104,
 1105*F*
 nuclei characteristics, 1099*T*
 oxygen-17 magnetic resonance
 spectroscopy (^{17}O NMR), 1100*T*, 1106
 phosphorus-31 magnetic resonance
 spectroscopy (^{31}P NMR), **1112–1117**
 adenosine diphosphate (ADP), 1114
 adenosine triphosphate (ATP), 1113,
 1113*F*
 analytical techniques, 1112
 brain research, 1115–1116
 cancer research, 1116–1117, 1117*F*
 characteristics, 1112
 creatine phosphate (PCr), 1114
 heart research, 1115
 human organ spectral data, 1113,
 1113*F*
 inorganic phosphate (P_i), 1113–1114
 liver research, 1116
 magnetisation transfer, 1113
 phosphodiester (PDEs), 1113, 1113*F*,
 1114
 phosphomonoesters (PMEs), 1113,
 1113*F*, 1114
 proton decoupling, 1113
 signal acquisition/spatial location,
 1112
 skeletal muscle analyses, 1114–1115,
 1114*F*
 rubidium-87 magnetic resonance
 spectroscopy (^{87}Rb NMR), 1100*T*,
 1105
 sodium-23 magnetic resonance
 spectroscopy (^{23}Na NMR), 1100*T*,
 1105
 xenon-129 magnetic resonance
 spectroscopy (^{129}Xe NMR), 1100*T*,
 1106
 iodine-127 magnetic resonance (^{127}I NMR)
 spectroscopy, **771–778**
 conducting and semiconducting lattices,
 777
 electric field gradient (EFG), 771–773
 food and nutritional science applications,
 678*T*
 general discussion, 771
 halide–cation interactions, 776–777
 halide–ligand interactions, 776
 nuclear properties, 771*T*
 quadrupolar interactions, 771–773, 772*F*
 residual dipolar coupling, 775
 shielding, 775–776
 spin–spin couplings, 774–775, 775*F*, 775*T*
labelled material studies, **1247–1254**
 carbon-13 magnetic resonance
 spectroscopy (^{13}C NMR), 1247–1249,
 1248*F*, 1249–1252, 1250*F*, 1254*F*
 endogenous metabolites, 1252–1253,
 1253*F*, 1254*F*
 exogenous metabolites, 1249–1252, 1250*F*
 general discussion, 1247
 hydrogen-1 magnetic resonance
 spectroscopy (^1H NMR), 1247
 hydrogen-2 magnetic resonance
 spectroscopy (^2H NMR), 1249
 nitrogen-15 nuclear magnetic
 spectroscopy (^{15}N NMR), 1249
 research areas, 1253–1254
 tritium magnetic resonance spectroscopy
 (^3H NMR), 2858
 lanthanum-138 magnetic resonance (^{138}La
 NMR) spectroscopy, 814–815
 lead-207 nuclear magnetic resonance (^{207}Pb
 NMR) spectroscopy, **798–811**
 applications, 809
 background information, 798
 chemical shift
 coordination number dependence,
 800–803
 effective nuclear charge, 803–804
 general discussion, 799–800
 interbond angle change effects, 804
 isotope effects, 799–800
 low-lying excited states, 803–804
 shielding ranges, 801*T*
 solvent dependence, 800
 substituent chemical shift effects,
 804–805

 future development areas, 8
 Metabolomics Standards Initiative (MSI), 5–8
 minimum information about a metabolomics experiment (MIAMET), 6
 minimum information about a microarray experiment (MIAME), 4
 minimum information about a proteomic experiment (MIAPE), 5
 standardized reporting guidelines, 2064
 Unified Modeling Language (UML)
 class diagram, 7*F*
 STOCSY-type experiments, 2062–2063, 2063*F*
- multidimensional (nD) NMR, 1721–1737
 applications
 general discussion, 1724–1726
 internuclear distance determination, 1727–1729
 nucleic acids, 1731–1734, 1732*F*
 protein dynamics, 1729–1731, 1730*F*
 protein spectra collection, 1726–1727
 protein structure determinations, 1725–1726, 1725*F*, 1726*F*
 synthetic macromolecules, 1733–1734
 very large protein correlation spectra, 1727, 1727*F*
- basic concepts
 heteronuclear 3D NMR, 1722–1724, 1724*F*, 1725*F*
 HNCOSY spectra, 1723–1724, 1725*F*, 2276*F*
 homonuclear correlation spectrum, 1722, 1723*F*
 spectral collection sequences, 1721–1722, 1722*F*
- biological applications, 1721
- data collection methods
 filter diagonalization method (FDM), 1734
 free induction decay (FID), 1734
 G-matrix Fourier transform (GFT) NMR, 1734–1736, 1735*F*
 maximum entropy method (MEM), 1734
 projection reconstruction methods, 1736, 1736*F*
 three-dimensional (3D) NMR, 1734
 historical background, 1440–1441
 peptide and protein orientation studies, 1508, 1508*F*, 1725*F*

- pulse sequences
 absolute value versus phase sensitive
 two-dimensional (2D) spectra,
 1850
 coherence pathway selection,
 1850–1852, 1851*F*, 1854*T*
 general discussion, 1849–1850
 gradient pulse sequences, 1852
 two-dimensional nuclear magnetic
 resonance (2D NMR)
 spectroscopy, 1849–1850,
 1849*F*, 1850*F*, 1851*F*, 1851*T*
- nitrogen-14 nuclear magnetic spectroscopy
 (^{14}N NMR), **1790–1799**
 characteristics, 213*T*, 429*T*
 chemical shift, 1790–1796, 1791*F*
 drug metabolism analyses, 431
 general discussion, 1790
 nitrogen shielding
 shielding ranges, 1791*F*
 solvent effects, 1796–1797, 1796*T*
 substituent effects, 1797, 1797*F*
- nuclear properties, 1790
 nuclear relaxation, 1799
 plant science applications, 2184*T*, 2187
 spin-1/2 NMR spectra, 2581–2582,
 2582*T*
 spin–spin couplings, 1797–1799
- nitrogen-15 nuclear magnetic spectroscopy
 (^{15}N NMR), **1790–1799, 1892–1898**
 applications
 general discussion, 1895–1896
 hydrogen bonding effects, 1897–1898,
 1897*F*, 1898*F*
 metal complexation, 1897, 1897*F*
 protonation, 1897, 1897*F*
 regioisomerism, 1896, 1896*F*
 tautomerism, 1896, 1896*F*, 1898*F*
 two-bond coupling constants, 1896,
 1896*F*
 characteristics, 213*T*, 429*T*, 1892–1893
 chemically induced dynamic nuclear
 polarization (CIDNP), 318*T*
 chemical shift, 1790–1796, 1791*F*,
 1892–1893, 1894*T*, 2073*T*
 cross polarization (CP) analyses, 1829,
 2588
 crystal polymorphism, 2240*F*
 drug metabolism analyses, 431
 future research areas, 1898
 general discussion, 1790
 interatomic distances, 1894–1895
in vivo applications, 1100*T*, 1104,
 1105*F*
 labelled material studies, 1249, 2273
 membrane studies, 1504, 1505*T*,
 1507–1508, 1508*F*
 nitrogen-15 (^{15}N) chemical shift tensors,
 1893–1894, 1894*F*, 1895*T*
- nitrogen shielding
 shielding ranges, 1791*F*
 solvent effects, 1796–1797, 1796*T*
 substituent effects, 1797, 1797*F*
 nuclear ^1H – ^{15}N coupling constants, 1893,
 1896*F*
 nuclear properties, 1790
 nuclear relaxation, 1799
 perfused organ research, 2105
 plant science applications, 2184–2186,
 2184*T*, 2187
 protein and peptide analyses, 1508–1509,
 1508*F*, 2273
 protein–ligand interactions, 1394,
 1397–1398
 relaxation mechanisms, 1895
 spin–spin couplings, 1797–1799
 system dynamics, 1895
 theoretical calculations, 1895
- NMR spectrometers, **1872–1880**
 background information, 1872
 future research areas
 coupled techniques, 1879–1880
 multipulse experiments, 1879
 sensitivity increases, 1879
 operation principles
 component diagram, 1873*F*
 continuous-wave (CW) mode,
 1872–1873
 decoupling process, 1876
 detection system, 1875–1876
 Fourier transform (FT) mode,
 1872–1873
 magnetic field optimization, 1874–1875
 magnets, 1873–1874, 1874*F*
 multidimensional NMR, 1441, 1877
 multiple pulse experiments, 1876–1877
 pulsed magnetic field gradients, 1878
 sample handling methods, 1874
 signal processing, 1875–1876
 special applications
 benchtop analyses, 1879
 magic angle spinning (MAS) NMR,
 1437–1438, 1878, **925–930**
 magnetic resonance imaging (MRI),
 1878–1879
 remote sensing, 1879
- nucleic acids, **1890–1891, 1992–2001**
 methodology, 1890
 molecular dynamics, 1999
 molecular interactions, 2000–2001
 resonance assignments, 1994–1996, 1995*F*
 sample preparation, 1992–1994
 secondary structure analyses, 1996, 1996*F*
 size limit considerations, 1999
 spectral assignments, 1890
 structural analyses, 1890–1891,
 2208–2211, 2210*F*
 structural data parameter extraction,
 1996–1997, 1997*F*, 1998*F*
 T7 RNA polymerase *in vitro*
 transcription, 1992–1994, 1994*F*
 three-dimensional (3D) structure
 determinations, 1997–1999
 triplex/quadruplex structures, 2000*F*,
 2001
- organic molecule structural analyses,
2718–2729
 carbon-13 magnetic resonance
 spectroscopy (^{13}C NMR), 2723–2727,
 2723*F*, 2724*F*, 2727*F*
 deuterated solvents, 2718
 general discussion, 2718
 hydrogen-1 magnetic resonance
 spectroscopy (^1H NMR)
 general discussion, 2718–2720
 proton chemical shift, 2718–2720,
 2719*F*, 2720*F*
 stereochemical assignments,
 2721–2723, 2722*F*
 through-bond spin–spin coupling
 analysis, 2720–2721
 methodology
 basic concepts, 2727–2729
 COSY spectral plot, 2725*F*
 HETCOR spectral data, 2727*F*,
 2728*T*
 product results, 2725*F*
 proton coupling constants, 2726*T*
 sample size, 2718
- oxygen-17 magnetic resonance spectroscopy
 (^{17}O NMR), **816–823**
 cell research, 220
 characteristics, 213*T*, 429*T*
 chemical shift studies, 2072*T*
 drug metabolism analyses, 431
 dynamic studies, 818
 experimental techniques, 816
 food and nutritional science applications,
 663*T*
 hydrogen bonding effects, 818
 indirect spin coupling constants,
 818
in vivo applications, 1100*T*, 1106
 kinetic studies, 818
 nuclear properties, 816, 816*T*
 nuclear quadrupole coupling constants
 (χ), 818
 shielding ranges, 816–818, 817*F*
 solid-state studies, 819

 nuclear properties, 798–799, 798*T*
 one-bond coupling constants
 $^1J(\text{E}, ^{13}\text{C})$ constants, 806
 $^1J(\text{E}, ^1\text{H})$ constants, 805
 $^1J(\text{E}, \text{transition metal})$ constants, 807
 $^1J(\text{E},\text{X})$ constants, 806–807
 general discussion, 805
 representative constants, 806*T*
 solid-state nuclear magnetic resonance (NMR) spectroscopy, 809
 spin-1/2 NMR spectra, 2582*T*
 vicinal coupling constants
 $^nJ(\text{E},\text{Y})$ constants, 808–809, 808*T*
 relaxation mechanisms, 808–809
 tritium magnetic resonance spectroscopy (^3H NMR), **2857–2860**
 advantages, 2857
 applications
 chiral methyl group analysis, 2858–2859
 macromolecular analysis, 2859–2860
 new tritium labelling reagents, 2858
 selective tritiation procedures, 2858
 substrate–receptor interactions, 2859
 nuclei characteristics, 2857
 sample preparation, 2857–2858
 tungsten-183 magnetic resonance (^{183}W NMR) spectroscopy, 812–813, 812*T*
 two-dimensional nuclear magnetic resonance (2D NMR) spectroscopy, **2861–2875**
 background information, 2861
 basic concepts
 COSY pulse sequence, 2864*F*
 COSY spectral plot, 2863*F*, 2864*F*
 data presentation, 2863–2864, 2863*F*
 experiment classifications, 2864–2867, 2864*F*, 2866*T*
 nuclear Overhauser enhancement spectroscopy (NOESY), 2862–2863, 2862*F*, 2866*T*
 spectral collection sequence, 2862–2863, 2862*F*, 2863*F*
 biofluid analyses, 129
 carbon-13 magnetic resonance spectroscopy (^{13}C NMR), 360–361, 360*T*, 361*F*
 experimental aspects
 acquisition conditions, 2867
 dimensionality reduction, 2874
 instrument requirements, 2867
 linear prediction, 2870–2871, 2871*F*
 phase cycling, 2868–2869, 2868*F*, 2869*F*
 pulse field gradients (PFGs), 2869
 quadrature detection, 2869–2870, 2870*F*
 selective excitation, 2872–2874, 2872*F*
 sparse sampling, 2871–2872, 2872*F*
 spectral resolution and data size, 2867–2868
 steady-state conditions, 2870
 time-proportional phase increment (TPPI) method, 2869–2870
 Fourier transform NMR spectroscopy, 1872–1873, 2861–2862, 2861*F*
 historical background, 1440–1441
 pulse sequences, 1849–1850, 1849*F*, 1850*F*, 1851*F*, 1851*T*
 sucrose analysis, 863*F*
 velocity flow, 1821, 1822*F*, 1823*F*, 1824*F*
 xenon-129 magnetic resonance spectroscopy (^{129}Xe NMR), **2949–2960**
 gaseous species, 2950–2951
 historical background, 2949
 hyperpolarized xenon, 2956–2959, 2957*F*, 2958*F*
in vivo applications, 1100*T*, 1106
 nuclear spin–lattice relaxation, 2950–2951
 nuclei characteristics, 2949–2950, 2950*T*
 probe capabilities
 clathrates, 2956, 2958, 2958*F*
 isotropic liquids, 2951–2952, 2951*F*, 2951*T*
 liquid crystals, 1353, 2952–2953, 2952*F*, 2953*F*
 molecular sieves, 2954–2956, 2955*F*
 polymers, 2953–2954, 2953*F*, 2954*F*, 2955*F*
 zeolites, 2954–2956, 2955*F*, 2956*F*, 2957*F*
 shielding effects, 2950–2951
 xenon compounds
 chemical shifts, 2959*F*
 general discussion, 2959–2960
 spin–spin couplings, 2958*T*
 ytterbium-171 magnetic resonance (^{171}Yb NMR) spectroscopy, 814–815
 zero-field NMR, 1370–1371, 1370*F*
 nuclear materials analysis, 89–90
 nuclear medicine, **15–22**
 background information, 15–16
 clinical imaging protocols, 16
 clinical single-photon imaging studies
 basic concepts, 2531
 bone scans, 18, 19*F*
 cardiac imaging, 17, 17*F*, 18*F*
 general discussion, 16–17
 image reconstruction
 filtered backprojection (FBP)
 reconstruction, 2536–2537, 2537*F*
 general discussion, 2536
 iterative reconstruction, 2537–2538, 2537*F*
 imaging equipment
 Anger cameras, 2532–2534, 2533*F*, 2534*F*
 Compton cameras, 2535, 2535*F*
 limitations, 2534–2535, 2535–2536
 next-generation systems, 2534–2535, 2534*F*
 system configurations, 2532*F*

 acetanilide, 1197*F*
 benzyl alcohol, 1195*F*
 cinnamonnitrile, 1196*F*
 general discussion, 1194–1196
 isobutyl methyl ketone, 1195*F*
 para-nitroaniline, 1196*F*
 vibrational frequency, 1188, 1189*F*
 vibrational interactions, 1188–1189, 1189*F*, 1190*T*
 interstellar and circumstellar molecules, 1070*T*
 nuclear magnetic resonance (NMR)
 spectroscopic analysis, **2718–2729**
 carbon-13 magnetic resonance spectroscopy (^{13}C NMR), 2723–2727, 2723*F*, 2724*F*, 2727*F*
 deuterated solvents, 2718
 general discussion, 2718
 hydrogen-1 magnetic resonance spectroscopy (^1H NMR)
 general discussion, 2718–2720
 proton chemical shift, 2718–2720, 2719*F*, 2720*F*
 stereochemical assignments, 2721–2723, 2722*F*
 through-bond spin–spin coupling analysis, 2720–2721
 methodology
 basic concepts, 2727–2729
 COSY spectral plot, 2725*F*
 HETCOR spectral data, 2727*F*, 2728*T*
 product results, 2725*F*
 proton coupling constants, 2726*T*
 sample size, 2718
 organic luminophores, 1379–1380, 1379*F*, 1380*F*
 organic pigments and dyes, 30*T*
organometallic compounds
 Fourier transform Raman spectroscopy, 739
 mass spectrometry (MS), **2047–2054**
 advantages, 2047
 metal complex analyses, 2047–2048, 2048*T*
 metal–ligand bond energies, 2051–2052
 neutralization–reionization mass spectrometry (NRMS), 1764*T*, 2053, 2053*F*
 remote functionalization mechanism, 2052–2053, 2053*F*
 spectral interpretation, 2048–2050, 2049*F*, 2050*F*
 thermochemistry, 2050–2051, 2051*F*
 organosilanes, 2542
 oriented bicelles, 1353
 Orion nebula, 1068*F*, 1535*F*
 ornithine, 131–135*T*
 orpiment, 29*T*, 32*T*, 33*F*, 34*F*
 orthophosphate, 1183*T*
 orthopyroxene, 421
osmium-187/189 ($^{187}\text{Os}/^{189}\text{Os}$), 815, 1976*T*
Oulu interferometers, 888
outer-volume suppression (OVS), 1090–1091, 1090*F*, 1094*F*
Overhauser effect (OE), 964–966, 964*F*, 1876, 2873–2874
oversulfated chondroitin sulfate (OSCS), 2335–2339, 2337*F*
oxalic acid, 1486*T*
oxaloacetate, 131–135*T*, 217*F*, 1253, 1253*F*
oxamide ((OCNH_2)₂), 564, 564*F*
oxaziridines, 1791*F*
oxazoles, 1791*F*
oximes
 chemical shift parameters, 362*T*
 shielding ranges, 1791*F*
oxirane, 2889
oxybuprocaine hydrochloride, 2241
oxygen-15 (^{15}O)-water, 2247, 2248, 2251–2252
oxygen (O)
 atomic mass, 1453*T*
 bulk biomedical concentrations, 174*T*
 cluster studies, 353, 353*F*
 interstellar abundances, 1075*F*
 isotopes
 delta (δ) values, 1229*T*
 isotope abundance ratios, 1229*T*
 isotope abundance variations
 characteristics, 1229–1230
 international reference water sample data, 1229*F*, 1230
 Rayleigh fractionation–water condensation plot, 1230*F*
 sample preparation, 1230
 isotopic composition, 416–417, 416*F*
 magnetic moment, 520*T*
 matrix isolation technique, 1481–1483, 1481*F*, 1482*T*
 nuclei characteristics, 1099*T*, 1976*T*
 observed frequencies, 1179*T*
 oxygen-17 magnetic resonance spectroscopy (^{17}O NMR), **816–823**
 cell research, 220
 characteristics, 213*T*, 429*T*
 chemical shift studies, 2072*T*, 2586*T*
 drug metabolism analyses, 431
 dynamic studies, 818
 experimental techniques, 816
 food and nutritional science applications, 663*T*
 hydrogen bonding effects, 818
 indirect spin coupling constants, 818
 inorganic structural analysis, 2710*F*, 2711*F*
 in vivo applications, 1100*T*, 1106
 kinetic studies, 818
 nuclear properties, 816, 816*T*, 2585*T*
 nuclear quadrupole coupling constants (χ), 818
 shielding ranges, 816–818, 817*F*
 solid-state studies, 819
 torsion angle, 818
 water orientation in lyotropic phases and bilayers, 818–819
 partial pressure studies, 924

oxygen (O) (*continued*)

scattering cross-sections, 1024*T*
selected-ion flow tube (SIFT) technique,
2526–2529

van der Waals radii, 2554*T*

oysters, 657–659*T*

ozone (O₃), 1480–1481

P

paint analyses, 682–683, 683*F*, 684*F*

Pake patterns, 2236

palladium (Pd)

atomic spectroscopic analyses, 2129–2131*T*

chemical shift ranges, 840

nuclear properties, 834, 835*T*, 1976*T*

short-lived radionuclides, 419*T*

palmitic acid, 1486*T*

palmitoylcholinephosphatidylcholine (POPC),
860*T*

pancreatic fluid, 129*T*

papayas, 672*T*

paper and ink analyses, 685, 686*F*, 687*F*

para-bis(trimethylsilyl)benzene (p-

C₆H₄[Si(CH₃)₃]₂), 457*F*

paracetamol, 947, 2418*F*

paradifluorobenzene, 3040, 3041*F*

paraffin, 362*T*

para-hydrogen-induced polarization,
969–970

*para*hydrogen-induced polarization (PHIP),
1659, 1660*F*

parametric amplification, 1901*T*, 1906*F*

para-nitroaniline, 1196*F*

partial least squares (PLS) analysis

chemometrics, 388*F*, 389

functional magnetic resonance imaging
(fMRI), 746–747

infrared (IR) spectroscopy

medical applications, 1498, 1499*F*

microbiological studies, 146

metabonomic studies, 1514, 1518*F*, 2064,
2064*F*

microbiological studies, 146

quantitative analysis, 2328–2329

particle-induced gamma emission (PIGE),
850–851, 851*F*

Paschen–Runge spectrometer, 72

pathological cyst fluid, 140–141

Paul Scherrer Institute (Switzerland),
1035–1037

peach leaves, 657–659*T*

pectins, 678*T*

pent-3-en-2-ol, CH₃CH=CHCH(OH)CH₃,
603*F*, 605*F*, 606–607

pentane (C₅H₁₂), 1456*T*

peptides

chromophore energy transitions, 168, 168*F*

circular dichroism (CD) spectroscopy

conformational transition analyses, 156,
158*F*

general discussion, 153–154

protein folding intermediate states,
156–157, 159*F*

protein folding kinetics, 157–158, 160*F*

protein folding thermodynamics,

154–156, 156*F*, 157*F*

protein–ligand interactions, 158–160,
161*F*

secondary structure analyses, 154, 155*T*

spectral data, 153*F*

vibrational circular dichroism (VCD),
2895

conformational characteristics, 2730–2731,
2731*F*

high-resolution NMR spectroscopy, 915

infrared (IR) spectroscopic analyses,
148–151, 150*F*, 151*F*

mass spectrometry (MS), 2089–2098

analytical methods

chemical derivitization, 2092–2093

collision-induced dissociation (CID),
2091–2092, 2092*F*, 2094*F*,
2280–2281

database searches, 2093–2094

detection sensitivity, 2090

direct analysis, 2091

in-gel digestion, 2093–2094

ionization methods, 2089–2090

liquid chromatography–mass
spectrometry (LC–MS) analyses,
2091, 2282, 2283*F*, 2320

matrix-assisted laser desorption

ionization (MALDI) mass

spectrometry, 2280–2281

molecular mass measurements, 2090,
2091*F*

sample preparation, 2089–2090

tandem mass spectrometry (MS–MS),
2322*F*, 2323*F*

applications

genetic mutation identification

processes, 2094

higher order structure analyses, 2057,
2095–2097

hydrogen–deuterium exchange

processes, 2097–2098, 2098*F*

noncovalent interactions, 2057,
2095–2097, 2097*F*

posttranslational modifications, 2095,
2096*F*

protein identification processes,
2093–2094

synthetic peptide/recombinant protein
quality control processes, 2093,
2094*F*

general discussion, 2098

research background, 570–572, 2089

(M–H)⁺ species fragmentation, 1751*F*

nuclear magnetic resonance (NMR)

spectroscopy, 2272–2279

data processing factors

general discussion, 2273–2274

multidimensional heteronuclear NMR
data, 2274–2276, 2275*F*, 2276*F*

one-dimensional (1D) NMR data,
2273–2274, 2274*F*

sequential assignments, 2274, 2275*F*,
2734–2736

triple-resonance assignments,
2274–2276, 2275*F*, 2276*F*

two-dimensional nuclear magnetic
resonance (2D) homonuclear
NMR data, 2274

general discussion, 2278–2279

heteronuclear 3D NMR, 1725*F*

historical background, 2272

internuclear distance determination,
1727–1729

labelled material studies, 2273

macromolecular conformational analyses,
2748–2750, 2749*F*

molecular dynamics, 2743

multidimensional (nD) NMR, 1725–1726,
1725*F*, 1726*F*

protein dynamics, 1729–1731, 1730*F*,
2278

protein folding, 2278

relaxation parameters, 2743, 2743*F*

sample preparation, 2273

solid-state nuclear magnetic resonance
(NMR) spectroscopy, 1508–1509,
1508*F*

spectra collection, 1726–1727

structural characterizations, 2730–2744

amide protein exchange, 2277–2278

amino acid sequences, 2272–2273,
2273*F*

chemical shifts, 2277

conformational characteristics,
2730–2731, 2731*F*

conformational parameter extraction,
2736–2737

coupling constants, 2277, 2738*F*, 2738*T*,
2739*T*

exclusive correlation spectroscopy
(E.COSY) technique, 2733*T*,
2739*T*, 2740–2741, 2741*F*

general discussion, 2276, 2730

HETLOC-type experiments, 2733*T*,
2734*F*, 2741, 2741*F*

hydrogen bonds, 2277–2278

nuclear Overhauser effect (NOE),
2736–2737, 2737*F*

nuclear Overhauser enhancement
spectroscopy (NOESY), 2274,
2275*F*, 2276, 2737–2738

residual dipolar couplings, 2277

rotating frame Overhauser effect
spectroscopy (ROESY),
2737–2738

sequential assignments, 2734–2736,
2735*F*, 2736*F*

signal assignments, 2731–2733, 2732*F*

signal shape analysis, 2738–2740,
2739*F*, 2740*F*

size considerations, 2272

spin system assignments, 2732–2733,
2734*F*, 2735*F*

structure derivations, 2278

structure determinations, 1725–1726,
1725*F*, 1726*F*, 2741–2743

very large protein correlation spectra,
1727, 1727*F*

proton affinities, 2847*T*

Raman optical activity (ROA) measurements
analytical methodology, 2369–2372

- bovine ribonuclease, 2365*F*, 2371*F*
 cytochrome *c*, 2373*F*
 general discussion, 2363–2365, 2385
 spectral data, 2372*F*, 2374*F*, 2375*F*, 2376*F*
 resonance Raman scattering (RRS) analyses

 inorganic structural analysis, 2713*F*
 in vivo magnetic resonance spectroscopy, 1112–1117
 adenosine diphosphate (ADP), 1114
 adenosine triphosphate (ATP), 1113, 1113*F*
 analytical techniques, 1112
 brain research, 1115–1116
 cancer research, 1116–1117, 1117*F*
 characteristics, 1112
 creatine phosphate (PCr), 1114
 heart research, 1115
 human organ spectral data, 1113, 1113*F*
 inorganic phosphate (P_i), 1113–1114
 liver research, 1116
 magnetisation transfer, 1113
 phosphodiesterases (PDEs), 1113, 1113*F*, 1114
 phosphomonoesters (PMEs), 1113, 1113*F*, 1114
 proton decoupling, 1113
 signal acquisition/spatial location, 1112
 skeletal muscle analyses, 1114–1115, 1114*F*
 magic angle spinning (MAS) NMR, 929, 2713*F*
 medical applications, 2212
 membrane studies, 1504, 1505*T*, 1506*F*, 1507*F*
 NMR spectrometers, 1878–1879
 nucleic acid structural analyses, 2208–2211, 2210*F*
 plant science applications, 2184*T*, 2186–2190
 protein complexes
 chemical shifts, 2211*T*
 general discussion, 2211
 phosphoglucosyltransferase (PGM), 2211–2212
 pH titration data, 2211*T*
 ribonuclease A (RNase A), 2211
 research areas, 2212
 signal assignments, 2206–2207, 2207*F*
 spin-1/2 NMR spectra, 2582*T*
 stray field imaging (STRAFI), 1649, 1650*F*
 phosphorus chloride (PCl_3), 775*T*
 phosphorus oxide (P_4O), 1480–1481
 phosphorus pentachloride (PCl_5), 1957, 1958*T*
 tin hexathiohypophosphate ($\text{Sn}_2\text{P}_2\text{O}_6$), 2244, 2244*F*
 trace element analyses, 657–659*T*
 tripolyphosphate, 1883*T*
 zirconium phosphate (ZrP_2O_7), 2244–2245, 2245*F*
 phosphotriesters, 2211*T*
 photoacoustic Raman spectroscopy (PARS), 1914–1916, 1915*F*, 1924–1926, 1924*F*
 photoacoustic spectroscopy (PAS), **2137–2145, 2146–2150**
 basic concepts, 2151–2158
 acoustic wave/thermal wave generation
 basic concepts, 2152–2153
 modulated PAS, 2153
 pulsed PAS, 2153–2154, 2154*F*
 general discussion, 2137, 2151, 2157
 heat release, 2151–2152, 2152*F*
 photoacoustic detectors
 light pulse excitation, 2156–2157, 2157*F*
 modulated light excitation, 2154–2156, 2155*F*, 2156*F*
 sensors, 2149–2150
 signal determinations, 2154–2156
 relaxation processes, 2152*F*
 signal generation, 2152*F*
 general discussion, 2146
 instrumentation
 cell design, 2149
 detection sensors, 2149–2150
 experimental setups
 gas-phase setups, 2148*F*
 general discussion, 2146–2148
 schematic diagram, 2147*F*, 2148*F*, 3051*F*
 modulation schemes, 2149
 radiation sources, 2148–2149
 photothermal spectroscopy, 2146–2148, 2147*F*, 2148*F*
 sample preparation methods, 1216, 1216*F*
 spectroscopic applications
 gas species analyses, 2140–2144, 2141*T*, 2142*F*, 2143*F*
 general discussion, 2137–2140
 life sciences studies
 blood serum and plasma, 2144–2145, 2144*F*
 food and nutritional science, 2145
 plant science, 2144–2145, 2145*F*
 liquid analyses, 2140, 2140*F*, 2141*F*
 solid materials, 2137–2140, 2138*F*, 2139*F*
 photochemically accumulated stimulated photon echo (PASPE), 944–945, 944*F*
 photochemically induced dynamic nuclear polarization (photo-CIDNP), 968–969, 969*F*
 photodiode array (PDA) detection, 980–981, 981*F*
 photodissociation mass-analysed ion kinetic energy (PD-MIKE) spectrometry, 1128
 photoelastic modulators (PEMs)
 circular dichroism (CD) spectroscopy
 single-beam design, 331–333, 332*F*
 vibrational circular dichroism (VCD), 2900, 2900*F*
 ellipsometry, 476, 476*F*
 infrared (IR) spectroscopy, 95
 photoelectron-photoion coincidence (PEPICO) spectroscopy, **2168–2175**
 characteristics, 2164, 2168
 electron energy analysis
 energetic electrons, 2169–2170
 threshold electrons, 2170

 environmental applications
 atmospheric measurements, 2078
 LIDAR (light detection and ranging), 2078
 water analyses, 2078–2079
 general discussion, 2087
 industrial applications
 cement industry, 2079
 cosmetics industry, 2079
 food and beverage industry, 2079
 general discussion, 2079
 pharmaceutical industry, 2080
 scattering cross-sections, 2498–2500, 2499*F*
mass, 452
momentum, 452–453
multiphoton absorption, 1319–1321
multiphoton excitation, **1682–1694**
 anion photoelectron spectroscopy, 1683*F*, 1690–1691, 1691*F*
 chemical trace analyses, 1692–1694, 1694*F*
 excitation schemes, 1682–1683, 1683*F*
 experimental setups, 1683–1685, 1684*F*
 general discussion, 1682
 laser desorption analyses, 1692, 1693*F*
 mass selective ion spectroscopy, 1683*F*, 1689–1692, 1690*F*
 multiphoton dissociation–tunable laser ion fragmentation analyses, 1683*F*, 1686–1689, 1687*F*, 1688*F*, 1689*F*
 resonance ionization spectroscopy, 1682, 1683*F*, 1685–1686, 1685*F*, 1686*F*
nonlinear optical phenomenon, **1899–1912**
 basic concepts
 characteristics, 1899–1901
 frequency characteristics, 1900*T*, 1901*T*
 independent nonvanishing elements, 1900–1901, 1903*T*
 ward and ladder graphs, 1902*F*
 four-wave mixing processes
 coherent anti-Stokes Raman spectroscopy (CARS), 1910–1911, 1910*F*
 degenerate four-wave mixing (DFWM), 1911
 general discussion, 1910–1911
 general discussion, 1899
 higher order electromagnetic effects, 1911–1912
 incoherent higher-harmonic scattering, 1912
 inorganic compounds
 metal vapours, 1908–1910
 noncentrosymmetric crystals, 1907–1908, 1909–1910*T*
 organic compounds
 liquids and solutions, 1901–1904, 1903*T*, 1904*T*
 organic layers and crystals, 1904–1905, 1905*F*, 1905*T*, 1906*T*
 phase matching, 1906–1907, 1907*F*
 photon energy conservation, 1905–1906, 1906*F*
 photon momentum conservation, 1906–1907
 SI unit conversions, 1911*T*
 non-resonant multiphoton ionization (NREMPI), 2508
 one-photon processes
 amplitude calculations, 2014*T*
 photoselection, 2019
 polarized absorption and emission, 2018–2019
 probability calculations, 2014*T*
 photoionization studies, 2177–2178, 2178*F*
 photon emission analyses, 2468
 polarization states, 453
 single-photon absorption, 1319
 single photon emission computed tomography (SPECT), **2531–2538, 2618–2619**
 applications, 2619
 basic concepts, 2531, 2618
 image reconstruction
 filtered backprojection (FBP)
 reconstruction, 2536–2537, 2537*F*
 general discussion, 2536
 iterative reconstruction, 2537–2538, 2537*F*
 imaging equipment
 Anger cameras, 2532–2534, 2533*F*, 2534*F*
 Compton cameras, 2535, 2535*F*
 limitations, 2534–2535, 2535–2536
 next-generation systems, 2534–2535, 2534*F*

 infrared (IR) spectroscopy, 2213–2220
 chemical property determinations
 polymerization reactions, 2217, 2218*F*
 spatial resolution, 2218, 2219*F*
 time-dependent phenomena, 2217–2218, 2219*F*
 forensic science applications, 689, 690*F*
 general discussion, 2213
 process control, 1021*F*
 spectroscopic considerations, 2213–2214
 structure determinations
 chain interactions, 2216
 general discussion, 2214
 polymer chain identification, 2214, 2215*F*
 processing-induced orientation, 2216–2217
 rotational isomers, 2215–2216, 2216*F*
 near-field scanning optical microscopy (NSOM), 2476, 2478*F*
 Raman spectroscopy, 2213–2220
 chemical property determinations
 polymerization reactions, 2217, 2218*F*
 spatial resolution, 2218, 2219*F*
 time-dependent phenomena, 2217–2218, 2219*F*
 general discussion, 2213
 mechanical property determinations, 2219
 spectroscopic considerations, 2213–2214
 structure determinations
 chain interactions, 2216
 general discussion, 2214
 polymer chain identification, 2214, 2215*F*
 processing-induced orientation, 2216–2217
 rotational isomers, 2215–2216, 2216*F*
 surface-enhanced Raman spectroscopy (SERS), 2826
 synthetic polymers, 2221–2236
 blend polymers, 898–899
 fluoropolymers, 898
 Fourier transform Raman spectroscopy, 24, 739
 magnetic resonance imaging (MRI), 2441*F*
 polyoxymethylene, 898, 898*F*
 poly(vinyl alcohol) (PVA), 897–898, 897*F*
 pyrolysis mass spectrometry (Py–MS), 2312–2313, 2312*F*
 solution-state studies
 carbon-13 cross polarization–magic angle spinning nuclear magnetic resonance (^{13}C CP–MAS NMR) spectroscopy, 894–897
 chemical identification, 2223–2224
 cross polarization (CP)
 analyses, 2228–2230, 2953–2954, 2954*F*
 dipolar decoupling (DD) analyses, 2228–2230
 dynamic and exchange NMR, 2231–2234, 2232*F*, 2233*F*, 2234*F*
 general discussion, 2223–2224, 2227–2228
 high-resolution magic-angle spinning (MAS) investigations, 2226–2227, 2226*F*, 2228–2230, 2229*F*, 2230*F*
 hydrogen-1 magnetic resonance spectroscopy (^1H NMR), 2227–2228, 2227*F*
 molecular weight determination, 2223–2224
 multidimensional NMR, 2230–2231, 2231*F*
 one-dimensional (1D) MAS method, 2233–2234, 2234*F*
 oriented polymers, 2235–2236
 relaxation studies, 2224–2226, 2225*F*
 separated local field (SLF) analyses, 2230–2231
 sequence analysis, 2224, 2224*F*
 spin diffusion NMR, 2234–2235, 2235*F*
 wideline separation (WISE) analyses, 2230–2231, 2231*F*
 structural characteristics
 architectural distinctions, 2221*F*
 basic concepts, 2221–2223
 bulk properties, 2222–2223
 schematic diagram, 2222*F*
 tacticity patterns, 2222*F*
 vibrational circular dichroism (VCD), 2897
 tritium magnetic resonance spectroscopy (^3H NMR), 2859–2860
 xenon-129 magnetic resonance spectroscopy (^{129}Xe NMR), 2953–2954, 2953*F*, 2954*F*, 2955*F*
 poly(methyl methacrylate) (PMMA), 898–899, 1215*F*
 poly(*n*-butyl methacrylate), 2229*F*
 polynuclear aromatic (PNA) compounds, 505–507, 505*F*, 506*F*, 507*F*
 polyoxymethylene, 898, 898*F*
 polypeptides, 153–154, 153*F*
 polypropylene, 361*F*, 655*T*, 2945*F*
 polypyridylruthenium(II) complexes
 electronic spectral data, 2625*T*, 2626*F*
 hydroquinone-containing ruthenium polypyridyl complexes, 2624–2625, 2626*F*
 mixed-valence states, 2624
 polysaccharides *see* carbohydrates
 polystyrene (PS), 1016*F*, 1018, 2215*F*, 2216*F*, 2233*F*
 poly(vinyl alcohol) (PVA), 897–898, 897*F*
 polyvinylchloride (PVC), 1652*F*, 2954, 2955*F*
 poly(vinylidene fluoride) (PVDF), 898–899
 polyvinyl methyl ether (PVME), 2954, 2955*F*
 pomace oils, 678*T*
 poppy seeds, 695

- porcelain, 655*T*
 pork, 657–659*T*
 porous material–fluid interaction analyses, 1630–1637
 background information, 1630
 flow velocity and diffusion measurements
 analysis results, 1635*F*
 methodology, 1634–1635, 1635*F*
 laboratory applications
 resolution factors, 1632
 standard imaging sequence, 1631–1632, 1631*F*
 stray field imaging (STRAFI), 1632
 three-dimensional Fourier transform (3D FT) imaging, 1632
 laboratory measurements
 cement paste analysis, 1634, 1634*F*
 chemical shift imaging, 1632, 1633*F*
 fluid saturation, 1632
 mud filtration, 1633–1634
 porosity, 1632
 relaxation times, 1632–1634
 surface wettability, 1633, 1633*F*
 oil well logging
 logging applications, 1636–1637
 logging tools, 1635–1636, 1636*F*
 relaxation properties
 Carr–Purcell pulse sequence, Meiboom–Gill modification (CPMG), 1631
 surface effects, 1630–1631
 susceptibility contrast, 1631
 porphyrins
 exciton coupling, 554, 554*F*, 555*F*
 laser desorption analyses, 1692, 1693*F*
 laser-induced optoacoustic spectroscopy (LIOAS), 1292–1294, 1293*F*, 1294*F*
 porphyrin–quinone electron transfer, 1294
 Portland cement, 1651*F*
 positive muons (μ^+)
 basic concepts, 1710–1711, 1711*T*
 polarization detection, 1711
 production processes, 1711
 positron emission tomography (PET)
 applications, 2247–2252
 cardiac studies, 2248

field desorption (FD) pyrolysis setup, 2307*F*
 pyrolysis vapour generator, 2308*F*
 applications
 bacteria, 2311–2312, 2311*F*
 natural products, 2308–2311, 2309*F*, 2310*F*
 synthetic polymers, 2312–2313, 2312*F*
 data analysis and reproducibility, 2308, 2308*T*, 2309*F*
 general discussion, 2301
 instrumentation, 2303*F*
 pyrrole, 1894*F*, 1895*T*
 pyruvate
 carbon-13 magnetic resonance spectroscopy (^{13}C NMR), 217*F*
 hydrogen-1 magnetic resonance spectroscopy (^1H NMR), 131–135*T*
 in vivo hydrogen-1 magnetic resonance spectroscopy (^1H NMR), 1110*F*
 pyruvic oxime, 1486*T*

Q

Q-switching lasers, 1338, 1917, 1917*F*
 quadratic discriminant analysis (QDA), 1705, 1707–1708
 quadrupole–inductively coupled plasma–mass spectrometry (Q-ICP-MS), 85*T*, 992, 2322–2324, 2323*F*
 quadrupole ion trap mass spectrometer, 1165–1173
 background information, 1165, 1456
 basic concepts, 1165–1166
 chemical ionization (CI), 1172–1173
 collision-induced dissociation (CID), 1172
 electrodes, 1166*F*
 general discussion, 1173
 historical background, 1166–1167
 ion molecule reactions, 1172–1173
 ion trajectory stability regions, 1169, 1169*F*, 1170*F*
 ion trap operation theory
 general discussion, 1167–1168
 Mathieu equation, 1168
 quadrupole field, 1167–1168
 stretched ion trap, 1168–1169
 laser ablation–inductively coupled plasma–mass spectrometry (LA-ICP-MS), 1265–1266
 metabonomic studies, 1669
 operation as mass spectrometer, 1171–1172, 1171*F*
 parabolic trapping potential, 1167*F*
 potential surface, 1170*F*
 protein and peptide analyses, 2055*T*, 2281–2282
 resonant excitation, 1170–1171
 scan function, 1172, 1172*F*
 schematic diagram, 1166*F*
 secondary ion mass spectrometry (SIMS), 2507–2508
 secular frequencies, 1169–1170, 1170*F*
 tandem mass spectrometry (MS-MS), 1172
 trapping potential well, 1167, 1168*F*
 qualitative fluorescence microscopy, 620
 quantitative analysis, 2325–2330
 analytical techniques
 chemometric methods, 2327–2328
 derivative spectroscopy, 2326–2327, 2327*F*
 single-wavelength data, 2326
 fluorescence quantitation, 2326
 general discussion, 2325
 light absorption characteristics, 2325
 multiple linear regression, 2328
 partial least squares (PLS) analysis, 2328–2329
 principal component regression (PCR), 2328–2329
 reflectance measurements, 2325–2326
 validation methods
 accuracy, 2329
 general discussion, 2329
 linearity, 2329
 precision, 2329
 robustness, 2330
 specificity, 2329
 quantitative fluorescence microscopy, 620
 quantitative NMR (qNMR), 2331–2339
 applications
 general discussion, 2335–2339
 impurity analyses, 2335–2339, 2337*F*
 background information, 2331
 basic concepts, 2331–2332, 2333*T*
 spectral analyses
 absolute measurement method
 internal standard method, 2334–2335
 normalization method, 2333
 relative measurement method, 2333, 2334*F*
 signal intensities, 2332–2333
 specificity and selectivity, 2335, 2336*F*
 quantum computing, 934–935
 quantum yield (Φ), 112
 quartz (SiO_2), 655*T*, 1909–1910*T*
 quasiequilibrium theory (QET), 720, 1464, 2689, 2692
 quasi-kinematic approximation, 463
 quassin, 551–552, 552*F*
 quercitron, 30*T*
 quinine, 2043
 quinoline
 chemical shift experiments, 366
 fluorescence spectroscopic analyses, 2043
 quinones, 1294

R

R^2T (rotational resonance tickling), 2602*T*
 R^2TR (rotational resonance in the tilted rotating frame), 2602*T*
 radiative Auger process, 3013, 3014*F*
 radical pair mechanism (RPM), 967–968, 967*F*, 968*F*
 radicals
 interstellar and circumstellar molecules, 1070*T*
 matrix isolation technique, 1479–1480
 neutralization–reionization mass spectrometry (NRMS), 1764*T*
 spectroscopic analyses, 2668–2674
 general discussion, 2668
 neon matrix–absorption spectroscopy
 analytical technique, 2668–2669
 instrumentation, 2668*F*
 radical-based electronic spectral data, 2670–2671, 2671*F*
 radioastronomy, 1533–1536, 1535*F*, 1536*F*
 radiofrequency muon spin rotation (RF- μSR), 1713
 radiogenic isotopes, 1225
 radioisotope excitation (RIXRF), 3001, 3008*T*
 radionuclides, 419*T*
 radiopharmaceuticals
 applications
 cardiac studies, 2248
 general discussion, 2247
 neurology studies, 2247
 oncological studies, 2248, 2248*F*
 therapy management, 2250–2252, 2250*F*
 nuclear medicine, 16, 17*T*
 radio waves, 451*F*, 455
 radiowave spectroscopy *see* microwave spectroscopy
 Raman, CV, 2938
 Raman-induced Kerr effect (RIKE), 1910*F*, 1914–1916, 1928*F*, 1928*T*, 1929, 1939*T*, 2946
 Raman optical activity (ROA), 2387–2396
 background information, 2358
 basic concepts, 2397–2405
 ab initio calculations, 2404–2405, 2404*F*
 biological applications, 2405
 energy level diagrams, 2399*F*
 far-from-resonance theory, 2400–2402, 2402*F*, 2402*T*
 general discussion, 2397
 general theory, 2399–2400
 observable interactions, 2399, 2399*F*, 2400*F*
 polarized light scattering, 2398–2399
 simple models, 2403–2404
 single electronic state theory, 2402–2403
 biochemical applications
 amino acids, 2362–2363, 2384–2385
 biological macromolecules, 2378–2386
 amino acids, 2384–2385
 carbohydrates, 2383–2384
 chiral enantiomer analyses, 2385
 crystal analyses, 2382–2383, 2383*F*
 dipeptides, 2385
 general discussion, 2378, 2405
 nucleosides, nucleotides, nucleic acids, 2385
 small molecule analysis, 2378–2382, 2379*F*, 2380*F*, 2382*F*
 carbohydrates, 2361–2362, 2383–2384
 dipeptides, 2385
 general discussion, 2361–2362, 2383–2384
 nucleosides, nucleotides, nucleic acids, 2365–2367, 2366*F*, 2373–2374, 2376*F*, 2385

 tetrahedral molecules, 1180*F*, 1181*T*
 tetraatomic molecules, 1180*F*, 1180*T*
 triatomic molecules, 1179*F*, 1179*T*
- intermolecular interactions, **957–962**
 hydrogen bonds
 acidity/basicity correlations, 959–960,
 960*F*
 bandwidth increases, 961
 bond length correlations, 958, 959*F*
 characteristics, 957–958
 concentration dependence, 958, 958*F*
 deuterium chloride–dimethyl ether
 (DCl–(CH₃)₂O) spectra, 958*F*
 energy of interaction, 959–960
 isopropanol spectra, 957*F*
 strong H–bond systems, 960–961,
 960*F*
 temperature dependence, 958
 thermodynamic quantity estimation,
 960
 liquid state interactions
 collisional interactions, 961
 solute–solvent interactions, 961
 matrix isolation technique, **1479–1483**
 anion analyses, 1479–1480
 cation analyses, 1479–1480
 characteristics, 1479
 experimental setup, 1479, 1479*F*
 free radical analyses, 1479–1480
 high temperature molecules, 1481–1483,
 1481*F*, 1482*T*
 intermolecular interactions, 961–962,
 962*F*
 laser-ablated vanadium atoms, 1482,
 1482*F*
 lithium superoxides (Li⁺O₂[−]), 1479–1480,
 1480*F*, 1480*T*
 molecular complexes, 1480–1481
- nonlinear Raman spectroscopy, **1913–1926**
 analytical methods
 general discussion, 1932
 scanned CARS, 1932–1933
 single-shot CARS, 1933
 spectral acquisition, 1932
 time-resolved nonlinear Raman
 spectroscopy, 1933
- applications
 coherent anti-Stokes Raman
 spectroscopy (CARS), 1910–1911,
 1917–1924, 1919*F*, 1920*F*, 1921*F*
 hyper-Raman scattering, 1917, 1917*F*,
 1918*F*, 1919*F*
 inverse Raman spectroscopy (IRS),
 1923*F*, 1924
 ionization-detected stimulated Raman
 spectroscopy (IDSRS), 1925*F*,
 1926
 photoacoustic Raman spectroscopy
 (PARS), 1924–1926, 1924*F*
 stimulated Raman gain spectroscopy
 (SRGS), 1922*F*, 1924
- basic concepts, **1935–1945**
 analytical techniques, 1939*T*
 energy level diagrams, 1937*F*
 general discussion, 1927–1929,
 1936–1938
 macroscopic nonlinear polarization,
 1940–1942
 microscopic origins, 1939*T*, 1942–1944,
 1943*T*
 signal field generation, evolution, and
 detection, 1939*T*, 1944
 theoretical principles, 1938–1940,
 1939*T*
- coherent anti-Stokes Raman spectroscopy
 (CARS)
 analytical techniques, 1939*T*
 applications, 1917–1924
 basic concepts, 1914–1916, 1927–1929,
 1928*T*, 1936–1938
 diacetylene spectra, 1921*F*
 energy levels, 1928*F*, 1937*F*
 four-wave mixing processes,
 1910–1911, 1910*F*
 laser instrumentation, 1930–1932,
 1931*F*, 1933*F*, 2946
 methane (CH₄) spectra, 1919*F*
 momentum conservation, 1916*F*
 rhodamine spectra, 1920*F*
 scanned CARS, 1932–1933
 schematic diagram, 1915*F*
 single-shot CARS, 1933
 temperature dependence effects,
 1920*F*
- coherent Stokes Raman spectroscopy
 (CSRS), 1910*F*, 1914–1916, 1915*F*,
 1928*F*, 1928*T*, 1929
- degenerate four-wave mixing (DFWM),
 1911, 1928*F*, 1928*T*, 1929
- experimental setup
 general discussion, 1929
 overlap, 1929
 phase matching, 1929–1930, 1930*F*
- general discussion, 1913
- hyper-Raman effect
 applications, 1917, 1917*F*, 1918*F*, 1919*F*
 basic concepts, 1913–1914, 1914*F*
- infrared sum frequency generation
 (IRSFG), 1928*F*, 1928*T*, 1929
- instrumentation, **1927–1934**
 analytical methods, 1932
 detectors, 1932
 general discussion, 1930–1932
 lasers, 1930–1932, 1931*F*, 1933*F*, 2946
 inverse Raman spectroscopy (IRS),
 1914–1916, 1915*F*, 1923*F*, 1924, 1937*F*,
 1939*T*
 ionization-detected stimulated Raman
 spectroscopy (IDSRS), 1916, 1916*F*,
 1925*F*, 1926
 laser instrumentation, 1930–1932, 1931*F*,
 1933*F*, 2946
 photoacoustic Raman spectroscopy
 (PARS), 1914–1916, 1915*F*, 1924–1926,
 1924*F*
 Raman-induced Kerr effect (RIKE),
 1910*F*, 1914–1916, 1928*F*, 1928*T*, 1929,
 1939*T*, 2946
 resonance coherent hyper-Raman
 spectroscopy, 1937*F*, 1938
 resonance Raman scattering (RRS),
 2426–2434
 advantages, 2429
 basic concepts, 2427–2428, 2428*F*
 characteristics, 2426, 2426*F*
 diatomic halogen molecules, 2429,
 2429*T*, 2430*F*
 general discussion, 2946
 heme protein analyses, 2429–2432,
 2431*F*, 2432*F*
 metalloporphyrin analyses, 2429–2432,
 2431*F*, 2432*F*
 molecular vibrational spectroscopic
 analyses, 2429, 2429*T*
 protein and peptide analyses,
 2432–2434, 2433*F*, 2434*F*
- stimulated inverse Raman scattering
 (SIRS), 2946
- stimulated Raman effect, 1914, 1914*F*
- stimulated Raman gain spectroscopy
 (SRGS)
 applications, 1924
 basic concepts, 1939*T*
 comparison studies, 1928*T*
 energy level diagrams, 1928*F*, 1937*F*
 general discussion, 1929
 high-resolution multi-pass spectral
 diagram, 1922*F*
 schematic diagram, 1915*F*
 third-order susceptibilities, 1914–1916
- stimulated Raman loss spectroscopy
 (SRLS), 1914–1916, 1915*F*, 1928*F*,
 1928*T*, 1929, 1937*F*, 1939*T*
- stimulated Raman spectroscopy (SRS),
 1910*F*
- surface-enhanced hyper-Raman
 spectroscopy (SEHRS), 1917
- surface-enhanced Raman spectroscopy
 (SERS), **2822–2827**
 advantages/disadvantages, 2824–2825
 biochemical applications, 2825
 biopharmaceutical research, 2665
 corrosion science applications, 2826
 forensic science applications, 2826
 general discussion, 2827, 2946

 photoionization studies, 2179
 planetary science investigations, 420–421, 420*F*
 protein and peptide analyses, 2090, 2281–2282
 resonance-enhanced multiphoton ionization (REMPI) analyses, 1696–1697
 schematic diagram, 2851*F*
 secondary ion mass spectrometry (SIMS), 2507–2508
 spatial focusing, 2853
 surface-induced dissociation (SID), 2778–2780, 2779*F*
 tandem instrumentation, 2855
 tandem mass spectrometry (MS–MS), 313, 1678, 1678*F*
 Wiley–McLaren focusing technique, 2853–2854
- time-proportional phase increment (TPPI) method, 2869–2870
- time-resolved electronic spectroscopy
 basic concepts, 1277–1280
 delayed coincidence photon counting, 1279*F*
 pump-and-probe technique, 1278*F*
 thermalization and recombination processes, 1278*F*
 wavepacket dynamics, 1278*F*
- time-resolved nonlinear Raman spectroscopy, 1933
- time-resolved Raman spectroscopy, 125, 125*F*
- tin (Sn)
 atomic absorption spectrometry (AAS), 51*T*, 2129–2131*T*
 hexachlorostannate, 1183*T*
 interstellar abundances, 1075*F*
 stannous bromide ($PbBr_4$), 775*T*
 stannous chloride ($SnCl_4$), 775*T*
 stannous iodide (SnI_4), 775*T*
 tin-119 (^{119}Sn) energy/de-excitation energies, 1566*T*
- tin-119 nuclear magnetic resonance (^{119}Sn NMR) spectroscopy, 798–811
 applications, 809
 background information, 798
 chemical shift
 coordination number dependence, 800–803, 802*F*
 effective nuclear charge, 803–804, 804*F*
 general discussion, 799–800
 halide species, 804*F*
 interbond angle change effects, 804
 isotope effects, 799–800
 low-lying excited states, 803–804
 shielding ranges, 800*T*
 solvent dependence, 800
 substituent chemical shift effects, 804–805
 temperature dependence, 800
 coupling constants, 805
 cross polarization (CP) analyses, 809
 experimental aspects, 799
 geminal coupling constants
 $^2J(E-X-^{13}C)$ constants, 808
 $^2J(E-X-^1H)$ constants, 807
 $^2J(E,Y)$ constants, 807, 807*T*
 miscellaneous couplings, 808
 long-range coupling constants, 808–809, 808*T*
 nuclear properties, 798–799, 798*T*
 one-bond coupling constants
 $^1J(E,^{13}C)$ constants, 806
 $^1J(E,H)$ constants, 805
 $^1J(E, \text{transition metal})$ constants, 807
 $^1J(E,X)$ constants, 806–807
 general discussion, 805
 representative constants, 806*T*
 solid-state nuclear magnetic resonance (NMR) spectroscopy, 809
 spin-1/2 NMR spectra, 2582*T*
 vicinal coupling constants
 $^nJ(E,Y)$ constants, 808–809, 808*T*
 relaxation mechanisms, 808–809
- tin hexathiohypophosphate ($Sn_2P_2O_6$), 2244, 2244*F*
- tin tetrachloride ($SnCl_4$), 1958, 1958*T*
- trace element analyses, 655*T*
- tip-enhanced Raman spectroscopy (TERS), 2462, 2462*F*
- tissue extract analyses
 disease diagnosis and characterizations, 2066–2067
- hydrogen-1 magnetic resonance spectroscopy (1H NMR)
 basic concepts, 925
 cellular environment analyses, 927
 future research areas, 929–930
 general discussion, 925
 liver sample spectra, 926*F*, 929*F*
 magic angle spinning (MAS) NMR, 925, 926*F*
 metabonomic studies, 2058–2059
 pulse sequence observing strategies, 927, 928*F*
 sample preparation, 925–926
- (partial) saturation recovery sequence, 404–406, 405*F*, 405*T*
 postmortem toxicology analyses, 696–697
- tissue perfusion
 arterial spin labelling, 1617
 dynamic contrast-enhanced magnetic resonance imaging, 1610–1611, 1617
 general discussion, 1616–1617
- titanium (Ti)
 anode properties, 2161*T*
 atomic absorption spectrometry (AAS), 51*T*, 2129–2131*T*
 barium titanate ($BaTiO_3$), 1909–1910*T*
 chemical shift ranges, 826*F*, 828*T*
 interstellar abundances, 1075*F*
 isotopic anomalies, 417, 417*F*
 lead zirconate titanate (PZT), 2146–2148, 2147*F*, 2149–2150
 nuclei characteristics, 825*T*, 1976*T*
 scalar coupling constants, 829*F*
 spectral characteristics, 830–831
 titanium oxides (TiO), 1481–1483, 1481*F*, 1482*T*
 titanium sapphire (Ti:sapphire) lasers, 1339*T*
- Titman–Keeler method, 2739*F*
- TOCSY-type experiments
 biofluid analyses, 129
 biomarker identification, 2062
 feature comparisons, 1954*T*
 organic molecule structural analyses, 2727–2729
 plant science analyses, 2185–2186
 protein and peptide analyses, 2274, 2732, 2732*F*, 2733*T*, 2734*F*, 2735*F*
 small molecule analysis, 2745–2746
 tissue extract analyses, 927
 two-dimensional nuclear magnetic resonance (2D NMR) spectroscopy
 data presentation, 2865
 experiment classifications, 2866*T*
 protein and peptide analyses, 2274
 pulse sequences, 1851*T*
 signal assignments, 2206–2207
 two-dimensional (2D) homonuclear analysis, 208
- m*-tolidine, 2628*F*, 2629*F*, 2630
o-tolidine, 2620–2621, 2621*F*, 2630
- toluene (C_7H_8)
 chemical shift imaging, 2345*F*
 gas-phase acidities, 2847*T*
 photoacoustic spectroscopy (PAS) analyses, 2143*F*
 toluene–cycloheptatriene radical cation rearrangement, 726–727, 727*F*
- xenon-129 magnetic resonance spectroscopy (^{129}Xe NMR), 2951*T*
- zero kinetic energy (ZEKE) photoelectron spectroscopy, 3045, 3045*F*
- toluidine blue, 1444*T*
- tomatoes, 672*T*, 1515*T*, 1517, 1518*F*
- topical skin protectants (TSPs), 2675–2679, 2676*F*, 2677*F*, 2678*F*, 2679*F*
- toroidal detectors, 1566*F*
- TOSCA indirect-geometry spectrometer, 1042, 1042*F*, 1769*F*

- total external reflection (TER) studies, 1570, 1570*F*, 1571*F*, 1591
- total internal reflectance fluorescence (TIRF) microscopy
- cell biology applications, 2460–2461
 - evanescent wave, 2458*F*, 2459*F*
 - implementation configurations
 - general discussion, 2460
 - prism-based TIRF, 2460, 2460*F*
 - prismless/objective TIRF, 2460, 2460*F*
 - intensity considerations, 2458–2460, 2459*F*
 - penetration depth, 2458
 - polarization considerations, 2458–2460, 2459*F*
 - single-molecule detection, 2461
 - surface plasmons, 2805, 2812
 - total internal reflection calculation, 2458, 2458*F*
- total reflection X-ray fluorescence (TXRF), 2996–2997, 2998*F*, 3002, 3004–3006, 3005*T*, 3006*T*, 3007*F*, 3008*T*
- Townes–Dailey approximation, 1959
- trace elements, 654, 680*T*
- trace gas analysis, 2523*F*, 2524*F*, 2525*F*, 2526–2529, 2526*F*, 2527*F*, 2528*F*
- trans*-1,2-dideuteriocyclobutane, 2890
- trans*-2,3-dimethyloxirane, 2890
- transferred-echo double resonance (TEDOR), 903
- transgenic foods, 1517, 1518*F*
- transient neonatal tyrosinaemia, 1488, 1488*F*, 1489*F*, 1490*F*
- transition metal ion doping, 1057–1058, 1059*F*
- transverse-field muon spin rotation (TF-μSR), 1711–1713, 1712*F*, 1713*F*, 1714–1716, 1714*F*, 1715*F*, 1717*F*
- transverse relaxation optimized spectroscopy (TROSY), 1727, 1727*F*
- traveling wave IMS (TWIMS), 1143–1144, 1143*F*

- electronic density redistribution, 2982, 2982*T*
- K α shifts, 2978–2979, 2979*T*, 2982, 2982*T*
- molecular orbital (MO) structural investigations
- basic concepts, 2976–2978
- energy levels, 2976*F*
- sulfate ions, 2977–2978, 2977*F*, 2978*F*
- SK α /SK β spectra research
- characteristic compounds, 2980, 2981*F*, 2981*T*
- thiocyanates/isothiocyanates, 2980–2981, 2981*F*, 2982*T*
- 3d atomic orbital investigations, 2979–2980, 2980*T*
- X-ray characteristics, 2984, 2984*F*
- X-ray fluorescence instrumentation, 2986, 2986*F*
- X-ray sources, 2986
- X-ray fluorescence (XRF) spectroscopy, **3000–3009**
- analytical characteristics, 85*T*
- applications
- cement analyses, 3003
- environmental analyses, 3004, 3004*F*, 3006*T*, 3008*T*
- fine art and archaeological objects, 3004, 3006*T*, 3008*T*
- general discussion, 3003, 3007
- geological analyses, 3003–3004, 3006*T*, 3008*T*
- lubricating oil analyses, 3003, 3006*T*, 3008*T*
- medical analyses, 3004, 3006*T*, 3008*T*
- metals and alloys analyses, 3003, 3006*T*, 3008*T*
- microfluorescence (MXRF) analysis, 3004, 3008*T*
- mining and ore processing, 3003, 3006*T*, 3008*T*
- sample preparation, 3002*F*
- synchrotron radiation-induced XRF (SRXRF), 3006–3007, 3008*T*
- total reflection X-ray fluorescence (TXRF), 3004–3006, 3005*T*, 3006*T*, 3007*F*, 3008*T*
- trace element analyses, 3003
- background information, 3000
- basic concepts, 2986–2987
- detection limits, 495
- detectors
- gas proportional (flow) counters, 2993, 2993*F*, 2995*T*
- general discussion, 2991–2992
- scintillation detectors, 2993, 2995*T*
- semiconductor detectors, 2993–2994, 2994*F*, 2995*T*
- X-ray detectors, 2992–2993
- energy dispersive X-ray fluorescence (EDXRF), 86, 86*T*
- forensic science applications, 84–86, 90

X-ray spectroscopy (*continued*)

- geological/mineralogical analyses, 759–760
- linear polarized radiation, 3002
- matrix correction methods, 2998
- monochromatic radiation
 - filtered radiation, 3001
 - general discussion, 3001
 - radioisotope excitation (RIXRF), 3001, 3008*T*
 - secondary target excitation, 3001
- nuclear materials analysis, 90
- radionuclide sources
 - β^- decay, 2991
 - electron capture, 2991
 - energy-dispersive X-ray fluorescence (EDXRF), 2991, 2992*T*
 - γ decay, 2991
 - selection criteria, 2991, 2992*T*
- research trends, 2998–2999
- sample preparation, 2998
- soil analyses, 499*F*
- spectrometers, **2989–2999**
 - basic concepts, 2989–2990
 - diffraction crystals, 2991–2992, 2992*T*
 - dispersion/detection units, 2991–2992
 - energy-dispersive X-ray fluorescence (EDXRF), 2991, 2992*T*, 2995–2996, 2997*F*, 2998*F*, 3001, 3008*T*
 - general discussion, 2961, 2989
 - microfluorescence (MXRF) analysis, 3002, 3004, 3008*T*
 - polarized X-ray fluorescence (PXRF), 2997–2998
 - radionuclide sources, 2991
 - sequential spectrometers, 2994–2995, 2996*F*
 - simultaneous spectrometers, 2995, 2997*F*
 - synchrotron radiation-induced XRF (SRXRF), 3002, 3006–3007, 3008*T*
 - total reflection X-ray fluorescence (TXRF), 2996–2997, 2998*F*, 3002, 3004–3006, 3005*T*, 3006*T*, 3007*F*, 3008*T*
 - wavelength-dispersive X-ray fluorescence (WDXRF), 2994–2995, 2995*F*, 3000–3001, 3008*T*
 - X-ray sources, 2990
- wavelength dispersive X-ray fluorescence (WDXRF), 86
- X-ray sources
 - anode materials, 2991*T*
 - general discussion, 2990
 - X-ray tubes, 2990, 2990*F*, 2991*F*, 2991*T*
- X-ray microanalysis, 2987
- X-ray photoelectron spectroscopy (XPS), 1308*T*
- X-ray tomography, **3021–3030**
 - advantages, 3028
 - artifacts, 3029–3030

- contrast media
 - air, 3027
 - general discussion, 3025–3027
 - intravenous contrast, 3026, 3028*F*
 - oral contrast, 3026, 3027*F*, 3030*T*
- dual modality imaging, 3027–3028, 3029*F*
- general discussion, 3030
- image generation
 - basic concepts, 3021, 3021*F*, 3022*F*
 - contrast media, 3025–3027
 - CT angiography (CTA), 3024–3025, 3026*F*, 3027*F*
 - CT numbers, 3021–3022, 3022*F*
 - Hounsfield units (HUs), 3021–3022, 3022*F*
 - image reconstruction, 3023–3025, 3024*F*, 3025*F*, 3026*F*, 3027*F*
 - multiplanar reformatting (MPR), 3023–3024
 - pitch, 3023, 3023*F*
 - three-dimensional (3D) imaging, 3024, 3025*F*
 - window level (WL) and window width (WW), 3022–3023, 3023*F*
- limitations, 3028–3030
- positron emission tomography/computed tomography (PET/CT), 3027–3028, 3029*F*
- xylylene, 1694*F*
- XYZ specifications, 382–383

Y

- yellow inorganic pigments, 29*T*
- ylides, 1764*T*
- ytterbium (Yb)
 - nuclei characteristics, 1976*T*
 - proton relaxation times, 1652*T*
 - ytterbium-171 magnetic resonance (^{171}Yb NMR) spectroscopy, 814–815
- yttrium (Y)
 - chemical shift ranges, 836, 836*T*
 - neodymium-doped yttrium aluminum garnet (Nd:YAG) laser, 1339*T*, 1917, 1917*F*
 - nuclear properties, 834, 835*T*
- yttrium (Yb), 51*T*

Z

Zeeman interaction

- applications, **3031–3034**
 - electric field measurements, 3033–3034
 - general discussion, 3031
 - parity-violation research, 3031–3033, 3033*F*
- atomic absorption spectrometry (AAS), 47, 62
- atomic emission theory, 65
- basic concepts, 532, 532*F*
- characteristics, 518–519, 519*F*
- instrumentation, **3035–3039**
 - atomic beam spectroscopy, 3035–3037, 3035*F*, 3036*F*, 3037*F*, 3038*F*

- coherent spectroscopy, 3038–3039
- general discussion, 3035
- laser magnetic resonance (LMR), 1297–1298, 1298*F*
- nuclear magnetic resonance (NMR) spectroscopy
 - electric field gradient (EFG), 771–773
 - hydrogen-1 magnetic resonance spectroscopy (^1H NMR), 320–321
 - quadrupolar interactions, 771–773
 - relaxation rates, 1856–1858, 1859*F*, 1860*F*
 - solid-state nuclear magnetic resonance (NMR) spectroscopy, 1813, 1814*F*, 1826–1827, 2587
- nuclear quadrupole resonance (NQR) spectroscopy, 1957–1959
- rotational resonance (RR)
 - basic concepts, 2596–2598
 - magnetization transitions, 2598–2599, 2598*F*, 2601*F*
 - see also* magnetic circular dichroism (MCD) spectroscopy
- zeolites
 - crystal structure analysis, 1051*F*, 1055*F*
 - Fourier transform infrared (FTIR) spectroscopic surface studies, 2816, 2817*F*
 - gas phase studies, 754–756, 755*F*
 - nuclear magnetic resonance (NMR) spectra, 754–756, 755*F*
 - powder diffraction pattern, 1053*F*, 1054*F*
 - Rietveld-analyzed powder diffraction pattern, 1054*F*, 1055*F*
 - structural evolution study, 1055*F*
 - xenon-129 magnetic resonance spectroscopy (^{129}Xe NMR), 2954–2956, 2955*F*, 2956*F*, 2957*F*
- zero-field muon spin rotation (ZF- μSR), 1712*F*, 1713
- zero-field NMR, 1370–1371, 1370*F*
- zero kinetic energy (ZEKE) photoelectron spectroscopy, **3040–3049**
 - basic concepts, **3050–3056**
 - background information, 2166, 3051–3055
 - delayed electric-field pulse techniques, 3051*F*
 - excitation schemes, 1701, 1701*F*, 3052*F*, 3053*F*
 - experimental setup, 2165*F*, 3055*F*
 - mass-analysed threshold ionization (MATI) technique, 2165*F*, 2166, 3055–3056
 - photoinduced Rydberg ionization (PIRI), 3056
 - pulse-slope risetime, 3054*F*
 - REMPI-photoelectron spectroscopy (PES), 3051–3052, 3052*F*
 - resolving power diagram, 3052*F*
 - Rydberg states, 2166, 3052, 3053*F*, 3054*F*
 - spectral intensities, 3055
 - experimental setup, 3055*F*
 - general discussion, 3040

- large molecule analysis
 benzene (C_6H_6), 3040, 3041*F*, 3043–3045, 3044*F*
 toluene (C_7H_8), 3045, 3045*F*
nitric oxide (NO) analysis, 3040, 3040*F*
paradifluorobenzene analysis, 3040, 3041*F*
small molecule analysis
 ammonia (NH_3), 3043, 3043*F*
 hydrochloric acid (HCl), 3042–3043
 iodine (I_2), 3040–3042, 3041*F*, 3042*F*
weakly bound molecules
 iodine–argon (I_2 –Ar) complex, 3046–3049, 3047*F*, 3048*F*
 phenol–methanol complex, 3045–3046, 3046*F*
zeta potential, 2087, 2087*F*
- zinc (Zn)
 ammoniacal copper, zinc arsenate (ACZA), 701*T*
 atomic absorption spectrometry (AAS), 51*T*, 2129–2131*T*
 chemical shift ranges, 826*F*, 828*T*
 chromated zinc chloride (CZC), 701*T*
 CZT (cadmium zinc telluride) detectors, 2532–2534
 essential trace element biomedical concentrations, 174*T*
 interstellar abundances, 1075*F*
 isotopic anomalies, 416–417
 metallomic studies, 183
 nuclei characteristics, 825*T*, 1976*T*
 pharmaceutical compounds, 2135*T*
 sample dilution factors, 176*T*
 spectral characteristics, 833
 spectral interferences, 175*T*
 trace element analyses, 655*T*, 657–659*T*
 white pigments, 29*T*
 yellow pigments, 29*T*
 zinc oxide (ZnO), 1909–1910*T*
 zinc selenide (ZnSe), 143*T*, 1210–1211, 1211*T*
 zinc sulfide (ZnS), 1211*T*
- zirconium (Zr)
 anode properties, 2161*T*
 chemical shift ranges, 836–837, 836*T*
 lead zirconate titanate (PZT), 2146–2148, 2147*F*, 2149–2150
 nuclear properties, 834, 835*T*, 1976*T*
 short-lived radionuclides, 419*T*
 zirconium phosphate (ZrP_2O_7), 2244–2245, 2245*F*
Z-scale, 445
